OF

VOL. LXIII

OF

“THE INDIAN MEDICAL GAZETTE”

ORIGINAL ARTICLES:—

	<i>Page</i>
Weil's Disease, as occurring in the Andamans. By V. N. Deuskar, L.C.P.S., I.M.D.	1
Conjunctivitis Vernalis or Spring Catarrh of the Conjunctiva. A Study of Seven Cases. By B. K. Narayana Rao, M.B., M.R.C.S. (Eng.), D.O. (Oxon.)	10
Dysentery in Secunderabad. By Capt. R. C. Wats, M.B., D.P.H., D.T.M., I.M.S., Capt. A. D. Loganadan, M.B., D.P.H., D.T.M. & H., I.M.S. and C. N. Conquest, I.M.D.	13
A Note on Indian Medicine. By the late Sir Clifford Allbutt, M.A., M.D., F.R.C.P., F.R.S.	53
Studies in Malaria, as it affects Indian Railways. By R. Senior-White, F.E.S.	55
A Simplified Method for Estimation of Sugar in the Blood. By J. P. Bose, M.B., F.C.S. (Lond.)	72
A Note on Stability of Solutions of Calcium Hypochlorite intended for Use in Snake-bite. By Lieut.-Col. A. D. Stewart, I.M.S.	76
The Value of Inoculation in the Prevention of Cholera. By K. L. Basu Mallik, M.B.	77
Some Laboratory Findings and Their Significance. By Lieut.-Col. J. W. D. Megaw, C.I.E., I.M.S., and M. N. Mullick, M.B.	113
Anæsthesia of the Splanchnic Area in the Surgery of the Upper Abdomen. By Major H. E. Murray, M.B., B.Ch. (T.C.D.), I.M.S.	117
An Intra-abdominal Operation for Oblique Inguinal Hernia. By Major P. Banerjee, I.M.S.	118
A Note on the Value of Rectal Injections of Potassium Permanganate in the Treatment of Pneumonia. By Lieut. A. Bayley de Castro, I.M.D.	120
The Antimony Test in the Early Diagnosis of Kala-azar. By Pasupati Bhattacharyya, D.T.M. (Bengal)	123
The Wassermann Test in India. By Lieut.-Col. R. B. Lloyd, M.A., M.B., B.Ch., I.M.S.	173
Genital Hypoplasia in Women. By Lieut. P. C. Dutta, M.B., F.R.C.S. (Edin.), D.G.O. (Dub.), I.M.S.	176
Difficulties in the Diagnosis of Fevers in the Tropics. By Major J. C. De, I.M.S.	177

ORIGINAL ARTICLES—(Continued).

Page

The Treatment of Bronchial Asthma with <i>Saussurea lappa</i> (Kuth Root). By Lieut.-Col. R. N. Chopra, M.A., M.D. (Cantab.), I.M.S.	186
An Outbreak of the Epidemic Dropsy Type of Beriberi in Allahabad, 1927. By R. N. Banerjee, M.B., B.S.	190
Sodii Salicylas and Rheumatic Affections. By Capt. P. V. Karamchandani, I.M.S.	192
A Note on the Intravenous Use of Urotropine in Influenza and Nephritis. By Amulya Kumar Bhattacharyya, L.M.P.	193
Chloroform Administration and Its Dangers. And the Rôle of the Epiglottis in Anæsthetic Collapse. By Lieut.-Col. F. J. Palmer, F.R.C.S.I., R.A.M.C. (Retd.)	194
A Preliminary Note on the Use of Ephedrine in Leprosy. By E. Muir, M.B., F.R.C.S. (Edin.), and S. P. Chatterji, L.M.S.	198
Indian Kala-azar in a Newly-born Child. By L. Everard Napier, M.R.C.S., L.R.C.P., and C. R. Das Gupta, M.B.	199
The Treatment of Fracture of the Femur. By Lieut.-Col. W. L. Harnett, M.A., M.B. (Cantab.), F.R.C.S. (Eng.); I.M.S.	233
Artificial Pneumothorax Treatment in India. An Analysis of 306 Cases. By C. Frimodt-Møller, M.B., ch.B. (Copenhagen)	241
Stock Solutions of Quinine. By Lieut.-Col. J. W. D. Megaw, C.I.E., I.M.S., Sudhamoy Ghosh, D.Sc., and N. R. Chatterjee, M.Sc.	244
The Treatment of Pernicious Anæmia by Liver. By Major J. B. Vaidya, I.M.S.	247
Plasmochin as Compared to Quinine in the Treatment of Malaria. By Capt. P. V. Karamchandani, I.M.S.	249
Urea-Stibol in the Treatment of Kala-azar. By Lieut.-Col. R. N. Chopra, M.A., M.D. (Cantab.), I.M.S., J. C. Gupta, M.B. (Cal.), M. N. Mullick, M.B. (Cal.), and A. K. Dutt Gupta, M.B. (Cal.)	252
Pathological Evidence Bearing on the Incidence of Diseases in Bombay. By P. V. Gharpure, M.D.	253
The Treatment of Cholera by Acid and Cresol. By Lieut.-Col. F. J. Palmer, F.R.C.S.I., R.A.M.C. (Retd.)	259
Microcephaly: A Report on "The Shah Daulah's Mice." By Major C. Lodge Patch, M.C., I.M.S.	297
Compression Fractures of the Spine. By Lieut.-Col. E. W. C. Bradfield, M.S., I.M.S., Capt. T. W. Barnard, M.S.R., F.R.P.S., and R. Mahadevan, M.B., B.S.	302
A Simple Rat-trap used by the Shan Villagers of the Northern Shan States, Burma. By Lieut.-Col. G. G. Jolly, C.I.E., M.B., D.P.H., D.T.M., I.M.S.	303
Tuberculosis of the Body and Cervix of the Uterus. By N. Gupta, M.B.	304
Tick-typhus and other Sporadic Fevers of the Typhus Group. By Col. J. W. D. Megaw, C.I.E., I.M.S., and S. Sundar Rao, L.M.P.	306
Seventeen Cases of Scarlet Fever. By Major P. Savage, I.M.S.	318
The Widal Agglutination Reaction in Healthy Persons. By Major A. N. Bose, I.M.S., and S. K. Ghosh Dastidar, M.B., D.T.M. (Bengal)	320
The Treatment of Psoriasis by Intramuscular Injections of Milk. By Shapurji Ardeshir Banker, M.D. (Bom.)	322
A Cataract Expression Operation. By Mano Mohun Roy	323
The Rate of Loss of Hookworm Eggs from Fæces. By P. A. Maplestone, D.S.O., M.B., B.S. (Melb.), D.T.M. (Liverpool)	324
Osteomalacia: Its Early Recognition, Modern Prevention, and Treatment: (A Three Years' "Follow Up" of 69 Private Cases). By Lieut.-Col. V. B. Green-Armytage, M.D., F.R.C.P. (Lond.), I.M.S.	357
A New Organic Aromatic Compound of Bismuth Suitable for Intravenous Injection in the Treatment of Frambæsia. By Lieut.-Col. R. N. Chopra, M.A., M.D. (Cantab.), I.M.S., J. C. Gupta, M.B. (Cal.), and M. N. Mullick, M.B. (Cal.)	361

ORIGINAL ARTICLES—(Continued).

Page

A. Simple Apparatus for Facilitating Radiography of the Limbs. By Capt. J. H. Barrett, I.M.S.	363
A. Special X-Ray Technique for the Examination of the Body of the Mandible. By Capt. J. H. Barrett, I.M.S.	364
Infestation of the Human Intestine by Corpoid Beetles in Bengal. By M. O. T. Iyengar	365
A Note on the Breeding and Habits of the Eye-fly, <i>Siphonella funicola</i> , Meij. By D. N. Roy, M.B., D.T.M. (Cal.)	369
Observations on the Antimony (Urea-Stibamine) Test for Kala-azar. By Major A. N. Bose, M.R.C.P., I.M.S., S. K. Ghosh Dastidar, M.B., D.T.M. (Bengal), and B. N. Bagchi, B.Sc., M.B.	370
Electro-cardiology and Some Observations on Indians. By Rai S. C. Banerjee Bahadur	372
Anæsthesia of the Abdomen. By Lieut.-Col. W. F. Brayne, B.A., M.B., Ch.B., I.M.S., and D. C. Sen Gupta, M.B. (Cal.)	381
Notes on a Case of "Black Tongue." By Richard Green, M.B., B.S.	381
Standards for Maclean's Urea Concentration Test in Healthy Indians. By Lieut.-Col. H. Stott, M.D., M.R.C.P., I.M.S., and V. S. Mangalik, M.B., B.S. (Lucknow)	384
Further Observations of the Epidemic Dropsy Form of Beriberi. By Col. J. W. D. Megaw, C.I.E., B.A., M.B., I.M.S., S. P. Bhattacharji, M.D., and B. K. Paul, B.Sc., M.B., D.T.M. (Bengal)	417
"Emergent Surgery" in Head Injuries. By K. M. Nayak, L.M. & S.	439
Tracheotomy for Diphtheria in Children. By Major P. Banerjee, F.R.C.P.S., I.M.S.	444
The Intensive Treatment of Kala-azar by Neo-Stibosan. By L. Everard Napier, M.R.C.S., L.R.C.P. (Lond.), and M. N. Mullick, M.B. (Cal.)	445
Rat-bite Fever as an Indian Disease. By Lieut.-Col. R. Knowles, I.M.S., and Assistant Surgeon B. M. Das Gupta	493
On Ether by the Open Method as the Anæsthetic of Choice in Indian Conditions. By Major J. B. Hance, M.A., M.D. (Cantab.), F.R.C.S.E., I.M.S., and Joti Pershad, L.M.P.	512
The Therapeutic Activity of Liquid Preparations of Ergot on the Calcutta Market. By Lieut.-Col. R. N. Chopra, M.A., M.D. (Cantab.), I.M.S., and Premankur De, B.Sc., M.B. (Cal.), M.R.C.P. (Edin.)	519
Experiments on the Digestibility of Different Kinds of Rice and Rice Preparations. By Shiam Narain Mathur, M.B., B.S.	521
Radiography as a Help to Correct Diagnosis in Traumatic Lesions. By Nisanath Ghosh	525
A Discussion on the Possibility of <i>Ascaris lumbricoides</i> Infection being Acquired Through the Skin. By P. A. Maplestone, D.S.O., M.B., Ch.B., D.T.M.	553
Report on the Investigation of an Outbreak of Epidemic Dropsy in Surada, a Village in Ganjam District. By A. V. Kamath, M.B., B.S.	555
An Outbreak of Epidemic Dropsy in Allahabad in 1927 (February to April). By G. Ghosh, M.B., B.S., D.T.M. (Bengal)	562
The Etiology of Green Diarrhœa of Infants: The Deficiency Factor. By R. K. Paul, M.Sc., M.B. (Cal.)	565
Late Manifestations of Syphilis without a History of Primary Sore. By A. C. Bharadwaj, L.M.P.	566
A Preliminary Note on the Decolourisation of a Solution of Methylene Blue when left in Contact with Kala-azar Serum. By Lieut.-Col. T. C. Boyd, I.M.S., and A. C. Roy, M.Sc.	568
Economic Significance of Malaria to an Industrial Concern: A Railway. By G. R. Rao, D.T.M. (Cal.)	568
Observations on 8 Cases of Blackwater Fever, Treated with Serums and Alkalies. By S. J. Bellgard, D.M.C. (Cal.), L.T.M., D.T.M. (Bengal)	573

ORIGINAL ARTICLES—(Concluded).

	Page
"Massage in the Treatment of Venomous Snake-bites." By Lucius Nicholls, M.D., B.C., B.A. (Cantab.)	574
Diphtheria an Ever-present Danger in India: A Report on a Series of Cases in Bilaspur District, Central Provinces, India. By V. C. Rambo, M.D.	575
Technique for Leishman's Stain Suitable for "Field" Application. By Capt. J. C. Chukerbuti, I.M.S.	578
An Epizootic in Squirrels at Kumbakonam. By K. S. Ranganathan, L.M.P.	578
A Plea for Vaginal Hysterectomy in India: Its Indications and Technique. A Record of 150 Consecutive Cases. By Lieut.-Col. V. B. Green-Armytage, M.D., F.R.C.P. (Lond.), I.M.S.	613
Prostatism. By Lieut.-Col. Sir James Reid Roberts, C.I.E., M.B., M.S., F.R.C.S. (Eng.), I.M.S. (Retd.)	617
The Nutrition of the Lens and Vitreous. By Lieut.-Col. Henry Smith, C.I.E., I.M.S. (Retd.)	619
Notes on the Use of Certain Preparations in Leprosy. By John M. Henderson, M.B., Ch.B. (Glas.), and S. P. Chatterji, L.M.S.	620
A Simplified Bed-side Blood-sugar Method. By Harendra Nath Mukherjee, B.Sc., M.B., D.I.C. (Lond.)	624
An Easy Method of Draining Inaccessible Suppurating Cavities. By S. Rama Iyer, L.M. & S. (Mad.)	626
The Diagnostic Value of a Monocytosis. By Lieut.-Col. H. R. Dutton, M.R.C.P. (Lond.), D.T.M. & H. (Camb.), I.M.S.	627
A Simplified Technique for Culturing Malarial Parasites Aerobically. By R. Row, M.D. (Lond.), D.Sc. (Lond.), O.B.E.	628
Plasmoquin in the Treatment of Malaria. By Pasupati Bhattacharyya, D.T.M. (Bengal), and S. P. Roy Chowdhury, L.M.P.	630
A Report on the Investigation into the Ætiology and Prevention of Naga Sore in Assam. By D. N. Roy, M.B., D.T.M. (Cal.)	673
A Critical Examination of the Antimony Tests for Kala-azar. By L. Everard Napier, M.R.C.S., L.R.C.P. (Lond.)	687
Malaria as a Cause of Cataract. By Major E. W. O'G. Kirwan, F.R.C.S.I., I.M.S.	697
Remarks on the Operability and Operative Technique of Vesicovaginal Fistula. By Kedarnath Das, C.I.E., M.D.	698
An Operation for the Radical Cure of Congenital Oblique Inguinal Hernia in Children. By Major P. Banerjee, F.R.F.P.S.G., I.M.S.	700
Report on Some Cases of Fibroids and Uterine Hemorrhages Treated by Radium. By K. S. Ray, M.A., B.Sc., M.B., Ch.B. (Edin.), M.L.C.	701

MIRROR OF HOSPITAL PRACTICE:—

A Case of Hydatid Cyst of the Liver. By Lieut.-Col. W. L. Harnett, M.A., M.B., F.R.C.S. (Eng.), I.M.S.	16
A Case of Probable Dermal Leishmaniasis. By Amulya Kumar Bhattacharyya, L.M.P.	17
Conjunctival Congestion after Urea-Stibamine Injection. By Nagendra Nath Roy, B.Sc., M.B.	17
A Case of Cerebral Malaria. By J. F. Henriques, L.M. & S., B.M.S.	18
Cases of Malaria in a Family. By Capt. S. B. Mukerji, M.B.	18
A Case of Retrograde Strangulated Hernia. By K. M. Nayak, L.M. & S.	19
An Unusual Foreign Body in the Pleural Cavity. By A. G. Pereira, L.M.S.	20
A Case of Malignant Malaria. By N. Chatterjee, M.B.	20
A Case of Aneurysm of the Common Carotid Artery at an Early Age. By P. A. G. Mudaliar, L.M.P.	21
Dysphagia as a Complication of Malaria. By Capt. C. C. Das Gupta, M.B.	21

MIRROR OF HOSPITAL PRACTICE—(Continued).

	Page
A Case of Submaxillary Calculus. By M. Umar	22
A Case of Unusual Foreign Body in the Oesophagus. By Babu Prasad Gupta, L.M.P.	22
A Case of Balantidial Dysentery. By Bijoy Krishna Chatterjee, M.B., D.T.M. (Bengal)	79
A Case of Cerebro-spinal Meningitis with Recovery. By Capt. K. M. Basu, M.B., late I.M.S.	80
A Case of Lymphatic Leukæmia. By J. M. Ghosh, M.B. (Cal.), D.P.H. (Lond.), D.T.M. & H. (Cantab.)	81
A Case of Imperforate Anus. By Indra Man	81
A Case of Chronic Amœbic Infection, Especially Affecting the Vermiform Appendix. By J. Ba Chow, L.M.P.	82
Apomorphine Hydrochloride in the Treatment of Persistent Hiccough. By R. C. Panda, L.M.P.	82
A Case of Recovery after Perforation of a Typhoid Ulcer. By J. Ba Chow, L.M.P.	126
A Folklore Charm against Bodily Injuries, Hypodermic Insertion of Gold Needles. By B. R. Sheno	127
A Case of Porro's Hysterectomy. By Mrs. B. E. Lewis, M.D.	127
Deep Infiltration Anæsthesia of the Orbit in Eye Operations. By R. A. Kalle, M.B., B.S.	128
Sodium Cacodylate in the Treatment of Boils. By Bidhubhusan Ghosh, L.M.F.	128
A Case of Melanotic Carcinoma. By B. R. Sheno, L.M.P.	129
An Interesting Case of the Lipoma of the Cheek. By Capt. B. P. Daruvala, M.C.P. & S. (Deolali)	129
A Note on the Intravenous Administration of Sodium Bicarbonate in Blackwater Fever. By Edmund Burke, L.R.C.P., L.R.C.S. (Edin.)	130
A Case of Melancholic Atonia or Psychocoma. By Lieut. A. Bayley de Castro, I.M.D.	132
Supra-pubic Cystotomy in a Case of Enlarged Prostate. By Bashiruddin Ahmed	200
A Case of Foreign Body in the Vaginal Mucous Membrane. By R. K. Rajagopalan	201
A Case of Incised Wound of the Lung. By A. S. Dawson, L.M.P.	201
Myiasis in a Leper. By G. R. Rao	201
On Some Clinical Features of Malignant Tertian Malaria. By Kali Gati Banerjee, M.B.	202
A Note on the Treatment of Cholera. By A. S. Dawson, L.M.P.	204
An Unusual Case. By Lieut.-Col. J. L. Lunham, I.M.S.	269
The Treatment of Simple Goitre with Sodium Iodide Intravenously. By Sarat Chandra Barooah, L.M.P.	270
A Case of Identical Delirium in Repeated Attacks of Blackwater Fever at Long Intervals. By Ronald Senior-White	271
Two Cases of Renal Tumour in Young Children. By Mrs. Satyapriya Mozumdar, M.B. (Cal.), L.R.C.P., M.R.C.S., F.R.C.S. (Eng.), L.M. (Dub.)	272
A Case of Spontaneous Rupture of Enlarged Spleen. By G. Raghunatha Rao	273
Atropine Sulphate in a Case of Strangulated Hernia. By P. M. Abraham, L.M.P.	273
A Case of Mycetoma of the Hand and Foot. By M. G. R. Row	329
Ascaris Infection Stimulating Bright's Disease. By J. C. Dutta	330
A Case of Lipomatosis. By D. R. Kumar	330
An Unusual Case of Lobar Pneumonia. By V. Sivamani	331
A Case of Congenital Dilatation of the Colon (Hirschsprun's Disease). By K. N. Dutta *	331

Food Infections and Food Intoxications. By S. R. Damon	542
Applied Biochemistry. By W. Morse	542
Diathermy: Its Production and Uses in Medicine and Surgery. By E. P. Cumberbatch	542
A Handbook of Histology. By A. McL. Watson	542
Ultra-violet Rays in the Treatment and Cure of Disease. By P. Hall	542
On the Dysenteries of India (with a Chapter on Secondary Streptococcal Infections and Sprue). By H. W. Acton and R. Knowles	543
Six Technical Lectures on Leprosy. Prepared by the Leprosy Department, Calcutta School of Tropical Medicine	544
Modern Medicine: Its Theory and Practice. By W. Osler and T. McCrae, Vol. VI	596
Acute Aplastic Anæmia: Its Relation to a Liver Hormone. By A. H. Smith	596
Tuberculous Intoxications. By J. Hollos	596
The Clinical Examination of the Lungs. By E. M. Brockbank and A. Ramsbottom	596
Nutrition and Diet in Health and Disease. By J. S. McLester	597
Diagnosis and Treatment of Diseases of the Stomach: with an Introduction to Practical Gastro-enteriology. By M. E. Rehfuß	597
Gynæcology. By H. A. Kelly	598
The Principles and Practice of Obstetrics. By J. B. De Lee	598
First Aid in Child-birth. By U. R. Rau	599
A Textbook of Actinotherapy: with Special Reference to Ultra-violet Radiation. By D. D. Rosewarne	599
Mental Disorders: A Handbook for Students and Practitioners. By H. J. Norman	599

REVIEWS OF BOOKS—(Concluded).

Page.

Introduction to Practical Bacteriology. By T. J. Mackie and J. E. McCartney	600
An Elementary Laboratory Guide in General Bacteriology. By H. J. Conn	600
Percival's Medical Ethics. Edited by C. D. Leake	600
How to Start in General Practice. By I. G. Briggs	601
The Genesis of Epidemics and the Natural History of Disease. By C. A. Gill	662
Modern Methods of Treatment. By L. Clendining	663
The Development of the Human Eye. By I. C. Mann	663
A Textbook of General Bacteriology. By E. O. Jordan	664
Systematic Infections: Their Diagnosis and Treatment. By A. K. Gordon	664
Some Principles of Diagnosis, Prognosis and Treatment. By R. Hutchison	664
Sterility in Women: Diagnosis and Treatment. By S. Forsdike	665
Radium in Gynæcology. By J. G. Clark, C. C. Norris and G. Failla	665
A Manual of Physics, Theoretical and Practical, for Medical Students. By H. C. H. Candy	665
Students' Handbook of Operative Dentistry. By R. Ahmed	666
An Introduction to the Technique of Section-Cutting from the Notes of the Late Mr. Peter Jamieson. By F. M. Ballantyne	666
Deafness and Its Alleviation. By V. Nesfield	666
Handbook of Diseases of the Nose, Throat and Ear, for Students and Practitioners. By W. S. Syme	666
Diseases of the Throat, Nose and Ear. By D. McKenzie	666
Practical Guide to Diseases of the Throat, Nose and Ear, for Senior Students and Junior Practitioners. By W. Lamb	666
Elementary Bacteriology. By E. Joseph and E. O. Greaves	667
Exposures of Long Bones and other Surgical Methods. By A. K. Henry	667
Baillièrè's Synthetic Anatomy. By J. E. Cheesman. (Part IX. Pterygo-maxillary Region)	667
The Basis of Sensation. By E. D. Adrian	667
The Radiography of the Chest. Vol. II. By W. Overend	667
Tropical Midwifery. By V. B. Green-Armytage	668
Surgical "Dont's" (and "Do's"). By C. H. Whiteford	668
Recent Advances in Surgery. By W. H. Ogilvie	668
Aids to Organic Chemistry. By S. F. Smith	668
A Manual of Surgical Anatomy. By C. R. Whittaker	668
Manual of Organic Chemistry for Medical Students. By S. Ghosh and T. C. Boyd	669
Aids to Public Health. By W. G. A. Robertson	669
Aids to Embryology. By R. H. Hunter	669
Quarterly Journal of Pharmacy and Allied Sciences. Vol. I, No. 1, January-March	669
Selected Papers on Injuries and Diseases of Bone. By W. I. de C. Wheeler	722
Treatment by Manipulation. By A. G. T. Fisher	722
The Eye. By C. W. Rutherford	722
Nasal Neurology, Headaches and Eye Disorders. By G. Sluder	723
Diseases of the Nose, Throat and Ear, for Practitioners and Students. Edited by A. L. Turner	723

ANNUAL REPORTS:—

Annual Report of the King Edward VII Sanatorium, Bhowali, U. P., for 1926	45
Report of the Health Officer of Calcutta for 1925	45
Annual Administration Report of the Asansol Mines Board of Health, for the year 1925-26	47

ANNUAL REPORTS—(Continued).

KOLYNOS DENTAL CREAM

(Made in England.)

Pregnancy.

The sore and sensitive mouth in an obstetric case is often of great concern. Food is masticated with difficulty and consequently the expectant mother is not receiving proper nourishment. The dentist may be able to give relief in the form of temporary operations, but the mother throughout the entire period should never neglect her teeth and mouth.

Kolynos Dental Cream on a DRY brush should be used faithfully after each meal, and particularly after vomiting. Not only are fermenting foods thus washed away, leaving a high degree of oral cleanliness, but the refreshing clean taste left in the mouth is highly appreciated. By not rinsing the mouth after brushing, some of the Kolynos remains in the interdental spaces and tends to exert a favourable influence in counter-acting acids and destroying bacteria. Correct brushing massages the gums and helps to keep them firm and healthy.

KOLYNOS Laboratories, London, ENGLAND
and New Haven, Conn., U.S.A.

On request our Distributors will gladly send you a dental package, free of charge.

WEIL'S DISEASE, AS OCCURRING IN THE ANDAMANS.*

By V. N. DEUSKAR, L.C.P.S., I.M.D.,

Haddo, Port Blair.

THE subject for to-day is Weil's disease, otherwise called infectious jaundice or spirochætosis icterohæmorrhagica—a fever with jaundice which has confused us in the Andamans for about the last 33 years and which has been from time to time described under various different names.

From the elaborate thesis of Lt.-Col. Barker, O.B.E., I.M.S., our former Senior Medical Officer, on "Leptospirosis" that appeared in the *Indian Medical Gazette* for October 1926, it will be seen that the existence of Weil's disease in the Andamans is now almost, *though not finally*, proved, and for this we all owe a debt of gratitude to him. Before proceeding with the subject proper I take it for granted that everyone of you present here to-day has gone through that thesis, and I would like to make it clear that in the present paper my only aim is to put before you a few facts with regard to the disease, as studied in a series of 23 cases treated in the wards of Haddo Hospital during 1926.

History.

Epidemics of jaundice have been reported to have occurred from very early times. Landouzy reported the occurrence of this disease in 1882 and Mathieu in 1886, Weil after whom the disease has been named without, it is said, enough justification reporting subsequently four cases. Valuable work however was done in 1914 by Inada and his colleagues who distinguished this disease from other forms of jaundice and put the etiology on firm basis by discovering the spirochæte concerned as the causative organism, and it was finally distinguished from yellow fever in 1918 by Noguchi's discovery of *Leptospira icteroides*, a similar spirochæte which he proved to be the causative organism of yellow fever.

Although Weil's disease is likely to be confused with various forms of fever with jaundice, that with which it is most likely to be confused is yellow fever; so much so that it may be impossible to distinguish one from the other on clinical grounds alone, since nearly all the symptoms that can occur in Weil's disease can also occur in yellow fever. Moreover, *L. icterohæmorrhagica* of infectious jaundice is not easy to find, and when found it is not easy to identify the spiro-

chætes for they are morphologically very closely similar to *Leptospira icteroides* of yellow fever. It is for these reasons that it becomes all the more necessary for us to substantiate our views in favour of the existence of Weil's disease in these islands by grounds other than such identification, and especially so because serological and immunological differentiation has so far not been attempted.

Considering the epidemiology of yellow fever, we find that for this disease to continue endemically in a place three conditions are required to be fulfilled, viz., there must be present

1. The causative organism: i.e., the *Leptospira icteroides*.
2. The vector: i.e., the mosquito concerned, *Aedes argenteus*, formerly known as *Stegomyia fasciata*. This species we know for certain exists in the Andamans.
3. The susceptible human beings.

Now when this is remembered and the mosquito population of the Andamans is taken into account, does it seem possible for yellow fever to continue endemically without any epidemic extensions?

Our experience of the disease prevalent here is that:—

- (a) Cases have occurred more or less sporadically;
- (b) The disease has not affected the new arrivals in any particular manner;
- (c) The white population has remained practically free; although a case here and there has been recorded;
- (d) It has never raged in any epidemic form; and
- (e) Our principal seaports of communication, viz., Calcutta, Madras and Rangoon, have not yet been invaded.

All these points are against yellow fever and the epidemiological importance of these cannot be ignored.

Coming to clinical considerations, we find that as yet no cases have been recorded which typically resemble yellow fever. The character of the disease here has been frequently described from as long ago as 1903, but so far none of the descriptions have pointed to the occurrence of the three stages of yellow fever or the characteristic "black vomit" of that disease. Are we then to believe that the cases that occurred over so many years last were all "atypical" cases of yellow fever? Such an assumption would be too far-fetched and can have no justification. As regards the black vomit, I may say that even in the fatal cases of yellow fever it may sometimes be absent during life, but its presence as a post-mortem finding is said to be almost invariable. But you will see that even in the most carefully conducted post-mortem examinations here in not a single case has its presence yet been recorded.

With all this negative evidence available, I think we can fairly exclude the possibility of yellow fever in the Andaman Islands.

* Being a paper read before the Clinical Society, Port Blair on 2nd March 1927, and published by the kind permission of Major J. M. R. Hennessy, I.M.S., Senior Medical Officer, Port Blair.

Definition.

As regards the definition of Weil's disease, Noguchi's seems to be the best. He describes it as "an acute, non-contagious disease caused by the invasion of a special organism *Leptospira icterohæmorrhagiæ* discovered by Inada and Ido in 1914. It is characterized by fever, jaundice, hæmorrhages and nephritis, and one attack usually confers complete and lasting immunity. The avenue of entrance of the organism is not known and animal experiments have shown that it is capable of penetrating the intact skin and mucous membrane of the alimentary tract."

Ætiology.—To be brief, *L. icterohæmorrhagiæ* is widely distributed in Nature. The natural reservoir is said to be the rat (*Rattus rattus* and *Rattus norvegicus*). The species we caught here belong to the former variety. The occurrence of the spirochæte in field rats explains why the disease is so common amongst the agricultural class, and it is through the urine and fæces excreted by these rats that the infection is stated to be generally carried to man. These leptospiræ have been found in slime in the roof of coal mines, in river and mud water, and even in drinking water and tap water. These water-leptospiræ are said to attain virulence on passage through such animals as monkeys, pups, rabbits and guinea-pigs, which are considered especially susceptible. Rat-fouled food is also said to be capable of producing the disease. But there may be some other and perhaps still more important and commoner factors responsible for conveying the disease to man, but they are so far not known. The leptospiræ are found in the urine, fæces, cerebro-spinal fluid and sputum of patients.

With regard to sex, the disease seems to be mainly confined to males, although its occurrence in females has been recorded. Here it is the occupation of the males that is primarily responsible, more than the sex. In Port Blair during the last two years we have not noted any case in the female sex and there seems to be so far no reference in the published records of the previous years to show that it ever occurred in women.

As regards occupation, those of the agricultural class and miners are said to be particularly liable. In Port Blair its occurrence has been noted amongst the self-supporting convicts of the cultivating class and others whose duty requires them to work in mud and water for prolonged periods. In the present series our experience is more or less the same. The occupation in the present series was as follows:—

Self-supporting cultivators	5
Free cultivator	1
Self-supporting garden coolies	3
Self-supporting road coolies	11
Self-supporting domestic servants	1
Self-supporting saw mill cooly	1
Munshi (self-supporter)	1

Out of these, the first twenty-one were exposed to mud and water for prolonged periods during work though their occupations seem to be slightly different, and so support the views held during previous years. The last two, however, were not exposed to any such conditions and in these cases careful enquiry strongly suggested that the infection must have been carried in a manner other than the usual one. For these reasons these two cases are interesting.

Locality.—During previous years the cases which have been reported occurred chiefly from the Western District. In the present series, however, they appear to have been more sporadic. The case distribution of the present series was as follows:—

<i>Eastern District.</i>		<i>Western District.</i>	
Phoenix Bay	.. 1	Naya-Shashr	.. 1
Middle Point	.. 2	Chatham	.. 1
Atlanta Point	.. 4	Wymberley Gunj	1
Phargaon	.. 8	Tusnabad	.. 1
Taylorabad	.. 1	Munglutan	.. 1
Aberdeen	.. 1	Port Moat	.. 1
—		—	
TOTAL	.. 17	TOTAL	.. 6

On these figures it would seem that most of the present series came from the Eastern District; but there may be fallacies in this. Atlanta Point includes the jail, and the cases here may have been admitted from the Western District, or a "carrier" imported from the same area. Taylorabad is practically Western District, or at least the conditions there are similar to those in the Western District. The men at Phargaon may have slept there, but during the daytime may have worked in the clay in the Western District or have been on jungle and forest labour there. Hence the difference in local incidence from previous outbreaks is not so marked as might at first sight be apparent.

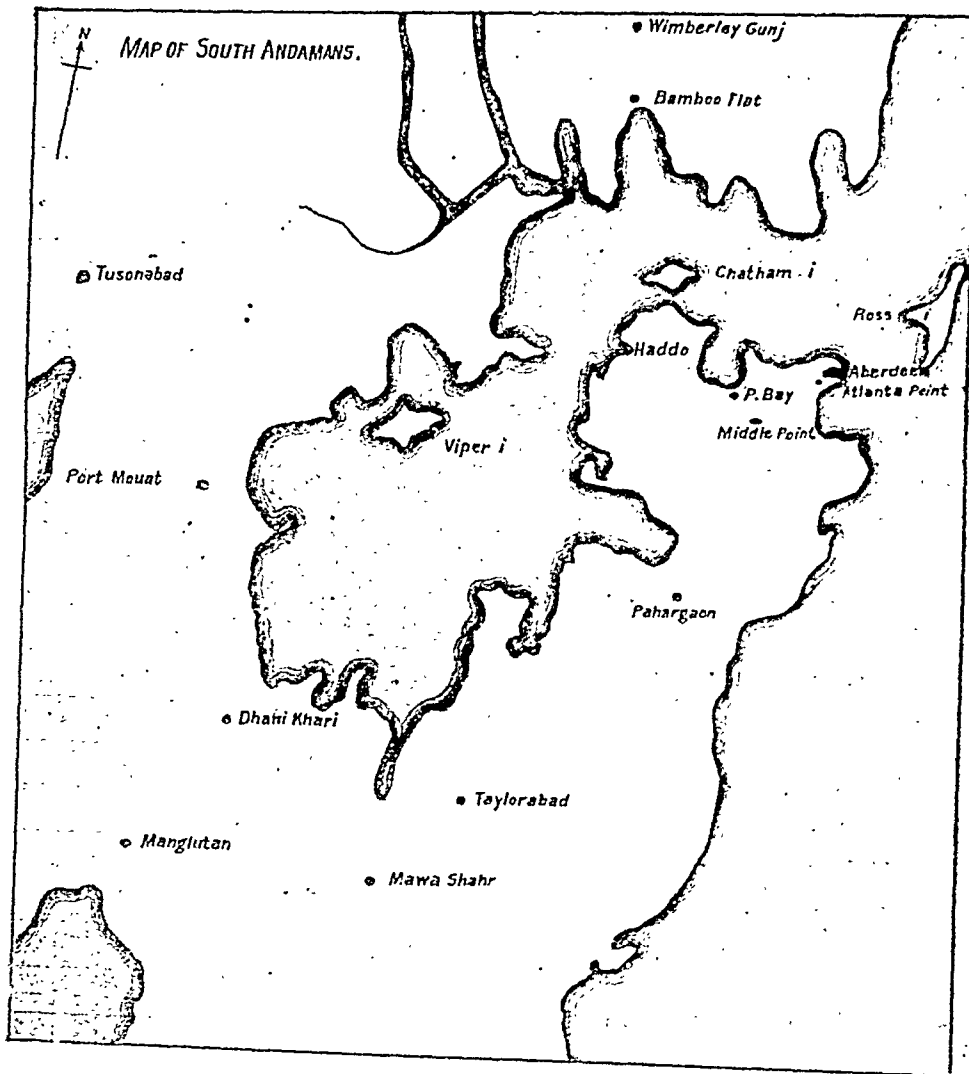

This also shows that the localities where the cases occurred were scattered all over.

Seasonal Incidence.—Cases have been stated to occur in the Andamans mostly from October to the end of January, although stray cases have also been stated to occur during September. In the series under reference however four cases occurred during the month of August which is of interest. References have been made during previous years to these cases being possibly of malarial origin. In this connection it is of interest to note that in the present series most of the cases of infectious jaundice occurred at a time when the malaria curve in the Settlement

was nearly at its lowest. This is shown by the following figures:—

Month.	Total number of cases Weil's disease.	TOTAL NUMBER OF MALARIA CASES.		
		Microscopic.	Clinical	Total.
June ...	0	35	12	47
July ..	0	76	24	100
August ..	4	71	39	110
September ..	3	48	55	103
October ..	11	14	36	50
November ..	4	15	33	28
December ..	1	6	18	24

F. The fever is said to last from three to eleven days, but is usually very irregular in character. Within a few hours of onset of the fever violent myalgic pains are complained of all over the body, neck, back, loins and limbs, those at the thighs and calves being about the worst, so much so that even the most gentle movements of the lower extremities make the patients shriek. With this there may arise restlessness, intense headache, constipation, nausea, vomiting and anorexia, and there is nearly always some prostration, which may vary according to the severity of the case. The temperature after the first two or three days may fall to normal, or may keep to about 101°F. or below. Then there comes on the injection of

The significance of the early or late rains and the amount of rainfall with regard to their relationship to the incidence of the disease seem to be an important but complex problem for practical study and investigation.

Symptomatology.—The incubation period is stated to be 5 to 6 days in experimental animals. It has varied from 6 to 13 days but is usually 6 to 8 days. To describe a typical case, the onset is sudden with fever ushered in by chills and rigors, the temperature rising to 103° or 104°

the conjunctivæ which may make the eyes look blood-shot, and by about the fourth day or a little later jaundice supervenes. This is first seen in the conjunctivæ, and later is generalised. It becomes progressively intense and may last for several days. With jaundice, nephritic signs and hæmorrhages may become evident, the latter occurring as epistaxis, hæmoptysis, hæmaturia and melæna. Spontaneous bleeding from the gums is common, and bright red blood may be passed with the stools when hæmorrhages occur.

lower down into the gut. There may be enlargement of the liver, which may be tender, and the same may happen, though rarely, to the spleen. The lymphatic glands (particularly the axillary and inguinal sets) may be enlarged and may be painful and tender. As regards the nervous symptoms there may be delirium (wild, or of the low muttering type), coma, and convulsions. The urine is scanty in the beginning, generally acid in reaction, and may contain albumin, bile, and tube casts. The pulse, though quick in the beginning, becomes relatively slow and is generally full and bounding. The respirations are usually hurried during the acute phase. By the second week a rash may develop, which it is said is generally confined to the chest but may cover the entire body. Secondary fever is not of infrequent occurrence but with this the symptoms are, as a rule, not aggravated. The tongue during the course of the disease usually shows a dark brown rather peculiar fur, which may be central or may cover the dorsum entirely. By the third week generally convalescence becomes established, its duration depending upon the severity of the case.

I shall now submit an analysis of the symptoms as were found present in the series under consideration.

Pyrexia.—This was "irregular" as will be seen from the temperature charts I have brought to show you. The temperature was in no case above 103°F ., and has usually kept to 101°F . or below. Secondary fever will also be noticed in a few cases; in one case on the 8th day, in another on the 11th, in two others on the 13th, and in the last case on the 31st day after the initial temperature first fell to normal. In connection with pyrexia the following points are important to remember:—

1. That the termination of the initial fever does not mean the setting in of convalescence. The temperature may drop to normal or sub-normal, yet the acute phase may continue and a fatal issue at this stage is not uncommon. Thus 2 of our fatal cases of this series and 2 fatal cases of the year 1925 had normal temperature on admission to hospital and shewed no rise at all up to the time of death;

2. It is therefore no real guide to the severity or otherwise of the case;

3. That by itself it is of little prognostic value; and lastly,

4. That with the onset of secondary fever there is no aggravation of the symptoms, nor is jaundice intensified—a feature directly opposite to that seen in yellow fever in its reactionary stage.

Pulse.—This in no case was "dangerously rapid" as has sometimes been described. Only one patient had a pulse up to 124 per minute. Usually quick in the beginning, it was subsequently slow, and in all cases it was full and bounding; but by this I do not mean to convey that there was any high blood pressure. Two

cases were admitted with intermittent and irregular pulse, yet in character it was full and

Misdiagnosed S. F. F.

bounding. These were put on to digitalis and did subsequently quite well.

No. 41499. (Recovery)
Name—Daudali Date of adm. 9-10-26.
Dis—Weil's disease,

Respirations.—These were generally accelerated, as will be seen from the charts in most cases.

Muscular pain.—This seems to be a very early and a very constant feature, and was absent in none. The pains set in with or within a few hours of onset of the fever. At any rate they

Prostration.—This seems to come on soon after the pains and varies in degree. The patient looks acutely ill and anxious, and seems to be in a state of exhaustion. Prostration of more or

No. 43660. Name—Sukha. Date of admission—11-10-26. Disease—Weil's disease. (Recovery.)

No. 46906. Name—Khazansingh. Date of admission—4-10-26. Disease—Weil's disease. (Result—Recovery.)

were not delayed more than twelve hours in any case. Although the pains were complained of all over the body those about the thighs and calves were particularly the worst, so much so that even the most gentle movements of the lower limbs made the patients shriek. Concomitantly there was complaint of a feeling of burning sensation all over the body, and about the urethral canal during the act of micturition by a few, and restlessness was common to all in varying degrees.

less severity was present in every case, and appeared to be a very constant and a striking early feature.

Injection of the Conjunctiva.—This also takes place very early, probably by the second day, but how soon after the first feeling of illness I cannot exactly say. No cases reported on the third day of illness, but in none of those admitted was it ever found absent on the third day of illness. Twenty cases had literally "blood-shot" eyes.

Two cases had it also, but in mild degree. The importance of conjunctival injection in the diagnosis of the disease is especially stressed by Buchanan in his recent monograph on it. The last case of the series was a sick transfer from Tushabad in whom the jaundice was so intense that the previous redness was completely replaced. In summing up the early and constant features I may say that before the supervention of jaundice, pyrexia, pains, and prostration plus conjunctival injection may be regarded as sufficient to warrant a diagnosis of Weil's disease in places where it is known to be endemic.

Jaundice.—This usually appeared between the fourth and the sixth day—in those cases however that developed it. Some of us perhaps cannot think of Weil's disease without thinking of the presence of jaundice, and it is here that I should

diagnosis of our so-called sandfly-fever,—cases which we have now no doubt were really cases of infectious jaundice. Out of a total of 23 cases those that developed jaundice were 14 in number, whereas 9 escaped it. These nine were mild in nature. The jaundice after its first appearance in the conjunctivæ begins to deepen and then becomes generalised. It then lasts for some days before it finally clears up. In our cases it lasted from seventeen to twenty days, but in two cases it took well over a month to disappear completely.

Tongue.—A dark brown fur which seems to be fairly peculiar was evident. It was sometimes central, with the edges clean, and sometimes covered the entire dorsum of the tongue.

Stools.—The characteristic stools of jaundice, i.e., white and clay coloured were encountered in only seven cases out of fourteen that developed

No. 46202. Name—Fazal Ilahi. Date of admission—13-10-26. Disease—Weil's disease. (Result—Recovery.)

like to emphasize the fact that jaundice, though frequently associated with should not be regarded as an invariable feature of Weil's disease, and that *absence of jaundice should not be interpreted as meaning absence of Weil's disease*. Indeed it is recorded that only 40 per cent of the cases in France during the Great War had jaundice. Cases can and do terminate at the stage of conjunctival injection, and these cases are as a rule mild; and it is here that the disease is most likely to be either completely overlooked or misdiagnosed as sandfly-fever or dengue, more especially the former. Thus five cases of our series that occurred from Phargaon in August and September were diagnosed as sandfly-fever. As these cases attracted our attention careful notes were kept, and it was the subsequent occurrence of two typical cases with intense jaundice (while some of the above cases were still in hospital) that suddenly disillusioned us as regards the

jaundice. The remaining sixteen—including seven cases with jaundice—had normal bile-stained stools.

Urine.—This was generally scanty and high coloured. In one case there was complete suppression, so much so that on catheterization not a single drop could be recovered. Prior to catheterization the patient complained of agonizing hypogastric pain, which evidently may have been partly due to the complete dryness of the mucous membrane of the bladder. This was a fatal case and died of both suppression of urine and a terminal pneumonia.

(a) Odour: Nothing peculiar; often aromatic; normal.

(b) Specific Gravity: This varied from 1010 to 1020.

(c) Reaction: Acid in 11, alkaline in 10, and in two specimens were not available (in one due to suppression).

(d) Albumen: Present in 9; absent in 12, specimens not available in two.

Absence of albumin and the alkaline reaction were probably due to large doses of alkalis and liberal fluid intake immediately after admission.

(e) Bile: It has already been mentioned that 14 cases only developed jaundice. It is rather surprising to find that bile reactions were positive in only four. In one no specimen was available, and 9 gave negative reactions, although visual examinations in every specimen pointed directly to the presence of bile. The reason why nine cases with jaundice should have failed to show the presence of bile on applying the usual tests is not exactly known. *Reference to the literature on infectious jaundice shows that in this disease bile may disappear from the urine at any time and it appears that it usually does so quickly.* This may be one of the reasons accountable for the negative reactions and hence the recommendation and the necessity for examination of urine between the fifth and the eighth day, when it is said that a drop or two of acetic acid to about an inch of urine gives an intense green reaction. In our cases I must confess that these examinations were not necessarily carried out between these days.

In this connection I should like to point out that some of the urines on being stood for over 12 hours separated out into two clearly visible layers, the upper one showing a greenish tint and the lower a dark or dirty brown. The significance of this, if any, is not known.

(f) Sediment: This was nearly always present in some quantity and under the microscope showed as:

1. Triple phosphates.
2. Stellar phosphates.
3. Tyrosin crystals.

(g) Tube casts: These were found in only one case.

Generally speaking, as the symptoms subsided the high coloured urine returned to the normal colour. No hard and fast rules could however be laid down in this connection, since in two cases the urine persisted to be highly coloured for over a month although these patients were otherwise quite well.

Hæmorrhages.—These were noticed in 8 cases.

Serial Nos. 1 and 19 of the table had hæmorrhages from the bowels. No. 9 had epistaxis. No. 11 had epistaxis and bleeding from the gums. No. 14 had epistaxis and profuse hæmorrhages from the bowels, kidneys and the gums which actually seemed to threaten death. An ophthalmoscopic examination by Dr. Naidu showed that he had retinal hæmorrhages also. No. 15 had bleeding from the gums and hæmoptysis of mild degree. No. 18 had also hæmoptysis lasting for three or four days. No. 23 had spontaneous bleeding from the gums, epistaxis, hæmoptysis, hæmatemesis and hæmorrhages from the bowels, of which the patient finally died.

Rash.—This was noticed in one case only, first appearing on the 10th day of the disease, more or less like a sudaminal rash. The same evening it became papular and well defined; next day it coalesced and became typically "measly," remaining so for a day more. The following day it slightly faded in colour and on the 14th day desquamation began, the skin peeling off in huge big patches almost the size of a palm. This went on for over a fortnight when desquamation was completed. The rash covered the entire body, but the mucous surfaces were free.

Enlargement of the Liver and Spleen.—Enlargement of both organs was noted in 10 cases, of the spleen alone in 4, and of the liver alone in 2 cases. The remaining 7 showed no enlargement whatever of either the spleen or the liver. Thus a total of 14 had splenic enlargements. Out of these 9 showed definite records of having suffered from malaria, attacks of which varied from one to thirteen in number. The remaining 5 had no records but their history showed that they had previously suffered from malaria. *Thus the splenic enlargement in practically all cases was undoubtedly of malarial origin.* It will be of interest to point out that out of the 4 who were new arrivals in Port Blair, the 2 who had enlarged spleens gave a history of having suffered from malaria. One had an attack in Port Blair two months previously, and the other suffered from it, he stated, while in Multan. Thus it will be seen that the enlargement of the liver (in 12 cases altogether) seems to be of frequent occurrence and this was often attended with some pain and tenderness.

Association of Malaria.—This was found present in one case only, blood examinations having showed malignant tertian crescents.

Hiccough.—This was present in one case at a time (16th day) when jaundice was also intense, but it was not continuous nor very severe.

Vomiting.—Moderate vomiting was seen in 8 cases.

Appetite.—Complete anorexia in the beginning was marked, but appetite was soon regained and became ravenous long before convalescence had set in. This rather unusual feature was most striking and was present in all the cases without an exception.

Insomnia.—This was usual but not of high degree; the pains accounting for it in the initial stage, and perhaps hunger for a period before convalescence had set in.

Nervous Symptoms.—Delirium was present in 3 cases; of the violent type in two and low muttering type in the other one; the latter had sub-sultus tendinium also. Coma and convulsions were not met with.

Special Senses.—Dimness of vision was complained of in one case that had retinal hæmorrhages, and deafness and ringing in the ears was complained of by another.

Serous Membranes.—One case developed dry pericarditis. He had much præcordial pain and distress.

Lymphatic Glands.—Suppurative parotitis requiring incisions developed in one case during the secondary fever. Enlargement of the lymphatic glands was not specially looked for, but in three cases lately seen at Bamboo Flat Hospital the axillary and the inguinal sets were found enlarged and tender.

Skin.—In all cases this was flushed and dry and was jaundiced in four. In one the jaundice was deep; in the other three it was moderate. There was no pruritus in any case. *Edema of the feet and ankles.* This developed suddenly in two cases, in one on the 13th and in the other on the 22nd day of illness, clearing up in one in about a fortnight and in the other in about 10 days. *This was an interesting and a rather unusual feature, as no reference to such edema seems to have been made in the literature on infectious jaundice.*

Blood Picture.—The red blood cells are destroyed and consequently reduced in number. It is said that the hæmoglobin value falls by about 50 per cent. There is some leucocytosis with an increase of the polymorphonuclears in the beginning, and later of the lymphocytes. Buchanan in his monograph on the disease emphasizes relative lymphocytosis as an important diagnostic feature in the disease, basing his view on the disease as observed in experimental animals.

In the present series enumeration of the red cells was not done. Total leucocyte counts were done once only on admission and so also the differential leucocyte counts. To be really instructive such examinations should have been carried out more frequently during the course of the disease. However, the results obtained were as follows:—

The total leucocyte counts varied from 3,125 to 36,256 per c. mm. and except for 4 or 5 cases, leucocytosis was not marked. The increase in the lymphocytes was however very striking. Of lymphocytes, if 23 per cent be regarded as a normal average, 20 of our cases had a definite lymphocytosis, 9 having shown quite 35 per cent or more. The hæmoglobin value recorded during convalescence showed reduction by about 30 per cent.

Case Mortality.—We had 3 deaths. This means roughly a mortality of 13 per cent, but this is not to be regarded as a general standard, for in 1925 we had 3 cases—all fatal—and this would mean a cent per cent mortality. It is said that the mortality varies in different countries but it seems that in one and the same place too it may vary within wide limits, depending upon the severity or otherwise of the cases concerned.

Diagnosis.—Detection of the organism under the dark ground is by far the best. The usual blood staining methods come next. Smears from specimens of centrifugalized urine could likewise be stained and a search made for the leptospiræ.

The acetic acid and Russo-methylene blue tests of the urine are valuable aids in diagnosis. Guinea-pigs may be inoculated intraperitoneally with 6 c.c. of the patient's blood, preferably within three days of onset, when the animal dies by about the 10th day of intense jaundice. Instead of blood the same quantity of a catheterized specimen of urine may be employed and this may prove useful even if done a little later, since it is said that the leptospiræ of Weil's disease may begin to appear in the urine from the 10th day onwards and may persist up to even 100 days.

Here it is important to remember that the positive findings are unfortunately rare and negative results are of common occurrence. A negative result therefore need not necessarily mean negation of the disease.

In the present series dark ground illumination was not done for want of a "star" lamp and in a few cases where search was made for the leptospiræ by staining methods this gave negative results. Intra-peritoneal inoculations were carried out in seven guinea-pigs, with blood in four, and with urine in three, including inoculating material from two cases which eventually terminated fatally. Three of our guinea-pigs died on the evening of inoculation or the following morning. They were all examined post-mortem, and no trace of visceral jaundice was evident. The remaining four are alive to this day and are perfectly healthy. These inoculations were done between the 3rd and the 27th day of the patients' illness. The results in the year 1925 were also the same.

Post-Mortem Appearances.—Briefly, there is universal congestion and intense jaundice. The latter involves practically everything and spares almost nothing. It involves the skin, mucous membranes—including that of the gut and the bladder—the conjunctivæ, the serosa, the deep tissues, and all the organs such as the heart, lungs, liver, spleen and the kidneys, which may be enlarged. The liver may be enormously enlarged and its weight may be twice or thrice the normal. It is usually firm on section and there is a moderate degree of fat necrosis present. The kidneys are similarly highly congested and enlarged and the weight may be double the normal or more. The bladder as an organ is jaundiced, including the lining mucous membrane inside. The brain and the meninges are not exempt. The jaundice involves even the bones, as becomes evident at the cut ends of the ribs while opening the thoracic cavity, so that everything appears highly congested and intensely jaundiced—so striking a post-mortem picture that once seen it can never be forgotten. Patches of inflammatory hyperæmia of varying sizes at the sites of hæmorrhages into the bowels, as may be expected are usual.

Differential Diagnosis.—(1) To yellow fever allusion has already been made. (2) The seven-day fever of Japan, although a leptospiral disease, is mild. There is no rash, no pains and

no mortality. (3) Sandfly fever is usually though not always a three-day or one-phase the patients suffering from the disease is important. To distinguish patients from

Serous Membranes.—One case developed dry pericarditis. He had much præcordial pain and distress.

The acetic acid and Russo-methylene blue tests of the urine are valuable aids in diagnosis.

vary within wide limits, depending upon the severity or otherwise of the cases concerned.

Diagnosis.—Detection of the organism under the dark ground is by far the best. The usual blood staining methods come next. Smears from specimens of centrifugalized urine could likewise be stained and a search made for the leptospiræ.

or inflammatory hyperæmia of varying sizes at the sites of hæmorrhages into the bowels, as may be expected are usual.

Differential Diagnosis.—(1) To yellow fever allusion has already been made. (2) The seven-day fever of Japan, although a leptospiral disease, is mild. There is no rash, no pains and

no mortality. (3) Sandfly fever is usually though not always a three-day or one-phase fever; besides the absence of jaundice, absence of mortality, absence of hæmorrhages and nephritic symptoms and presence of pains behind the eye-balls are important. (4) In dengue the joint pains, the terminal rise of temperature making up the two-phase fever, the rash and the epidemicity are classical features. Besides, it is as a rule not a fatal disease, and jaundice is absent. (5) In black-water fever, paroxysms of fever, hæmoglobinuria, and increase in the large mononuclears are characteristic. (6) Relapsing fever need present no difficulties. The *Spirochaeta recurrentis* is very different from the leptospiræ and is very easily recognised. Besides there are no blood-shot eyes, no hæmorrhages, and the jaundice is not so intense. The temperature chart is also characteristic and salvarsan preparations bring about a magical cure. (7) In acute yellow atrophy reduction in the size of the liver, as opposed to the enlargement of the same organ in Weil's disease, should be remembered. (8) And lastly as for catarrhal jaundice I may say that the course of this disease will at once settle the diagnosis.

Treatment.—Absolute rest, careful nursing, a preliminary purge, large doses of alkalies, a very liberal fluid intake, and early fomentations over the loins for fear of suppression of urine are all of great benefit. Pains may be relieved in the usual way, and so also the hæmorrhages. It is said that nothing is more useful for the latter and our own experience was also the same.

Polyvalent anti-leptospira serum in 20 c.c. doses, at several hours interval, at least four times in succession is said to be by far the best treatment. In the absence of this, sera from convalescent patients may be employed in the same doses.

Careful dieting before and during the convalescence is necessary, and it should be carefully borne in mind that the ravenous appetite is untimely. Fats are not to be recommended.

The salvarsan preparations are of no use and presumably also the mercurials.

The treatment in the present series consisted of sodium salicylate injections, 10 grains in 10 c.c. of water intravenously on the first two days, and large doses of alkalies by mouth, combined with sodium salicylate and ammonium chloride.

For hæmorrhages, chloride or lactate of calcium by the mouth and injections of adrenaline were employed, but without any significant result.

In 4 cases serum from convalescent patients was used in from 1 to 4 c.c. doses intravenously. But the dose employed was too small to study the therapeutic effects.

Prophylaxis.—This resolves itself into waging war against rats. Drainage of the soil, where possible, is also recommended. Adequate disinfection and incineration of fæces and urine of

the patients suffering from the disease is important. In discharging patients from the hospital it has to be remembered that the *Leptospira icterohæmorrhagica* is capable of persisting in the urine up to 100 days into convalescence and therefore such patients may possibly act as carriers of the disease during this period, and may consequently materially help the spread of infection.

Conclusion.—In conclusion, I shall only draw your attention to the three special features of this series and these are:—

1. The seasonal incidence;
2. The locality with regard to the occurrence of cases; and
3. The absence of jaundice in mild cases (39 per cent).

(1) This is the first time that cases are reported to occur in the month of August. (2) As to the locality one and all the cases of Lt.-Col. Barker's series from 1921 to 1924, occurred invariably from the Western District. It is remarkable that a large number of cases of the present series occurred from the Eastern District area, including fatal and severe cases. (3) Thirdly, the occurrence of mild cases terminating at the stage of conjunctival injection (i.e., without developing jaundice) is of special interest. Whether such cases were encountered by Lt.-Col. Barker or not I do not know, but no reference to any such cases seems to have been so far made by him or anyone else previously in the Settlement. As the diagnosis of such cases would be debatable, it is possible that the inclusion of the most typical cases only in the series would have been considered justifiable or else it is possible that they were overlooked. During Lt.-Col. Barker's time I hear there used to be a standing order for all the cases of jaundice to be evacuated to Ross Island from outside hospitals. And if the order evidently referred to cases of jaundice only, it is not surprising that cases where there was no jaundice were either lost sight of or misdiagnosed.

Stokes, Ryle, and Tytler, reporting on Weil's disease in the British Army in Flanders state that "of 47 cases diagnosed as Weil's disease, clinically or by communication of the disease to animals, 74 per cent developed jaundice and 26 per cent have not shewn any coloration." In another place they state: "We cannot say definitely in how many cases of Weil's disease jaundice occurs as a clinical sign, but we estimate that it does not occur in more than 60 per cent of cases in the epidemic with which we are dealing."

CONJUNCTIVITIS VERNALIS OR SPRING CATARRH OF THE CONJUNCTIVA.

A STUDY OF SEVEN CASES.

By B. K. NARAYANA RAO, M.B., M.R.C.S. (Eng.),
D.O. (Oxon.),

Superintendent, Minto Ophthalmic Hospital, Bangalore, and Professor of Ophthalmology, University of Mysore.

VERNAL catarrh of the conjunctiva is not really rare in this part of South India, a large number of cases escaping notice being mistaken for other more common forms of conjunctivitis which occur in large numbers about the same time of the year as this disease, namely, April to July. Though not so destructive of vision as trachoma with its numerous complications and sequelæ, yet its annoying and often distressive symptoms, its chronic course—sometimes extending to several years—its great refractoriness to treatment, its occurrence in the educational period of life—involving economic loss—its wide difference from other affections of conjunctiva in regard to its causation, prognosis and treatment—all these call for a careful observation and study of this disease.

The disease was first described by Arlt of Vienna in 1846. (1) Saemisch (1876) named it "Spring Catarrh of the Conjunctiva" from its seasonal occurrence and exacerbation. Horner (1889) described the characteristic growth on the tarsal conjunctiva. Herbert (2) (1903) described the eosinophilic infiltration of the new tissue and the eosinophile increase in the blood.

Having discovered two cases in the early part of 1926, my assistants and myself watched for cases in the summer and picked out a number of probable cases whose conjunctival discharges were examined, and a number who were definitely diagnosed as suffering from vernal catarrh were kept under close observation and studied in greater detail. The observations in 7 such patients have been tabulated in the accompanying statement. In all cases a fairly comprehensive examination of the entire system was made, including analysis of the urine, examination of the fæces for helminths, of the blood cell picture, coagulation time, and sometimes also for the Wassermann test. These cases were observed for periods ranging from three weeks to four months, except Case No. VI who is an old case under my observation for last 8 years. Besides this series of 7 cases, there have been 10 others treated subsequently in this institution on whom general observations have been made without a detailed study.

The main points noticed were:—

(1) *Heredity, etc.*—There was no hereditary or familial tendency in any case, other children—sometimes brothers or sisters—living under identical conditions being unaffected. There was no hereditary syphilis and the Wassermann reaction was negative when tested.

(2) *Sex and Age.*—All the 7 were males between 14 and 20 years of age. In the subsequent 10 cases 9 were adolescent males and one a female aged 20 years.

(3) *Occupation, Climate, Season, etc.*—Of these seven, 6 were students, one an agriculturist. Of the subsequent ten, 8 were students, one a house-wife and one a cook. Of the 7+10=17 cases one came from Trichinopoly with a hot climate, 15 from the various parts of the Mysore plateau, and one from Coimbatore belonging to the same region. All the 7 cases came in the summer, though other cases have come less frequently all round the year. Most of the patients complained of worse symptoms in summer and relief on the occurrence of rains.

(4) *Diet and Habits.*—All were strict vegetarians, except one subsequent case who was a Mahommedan. Most were town-bred high caste Hindus.

(5) *Toxæmias, Infection, etc.*—All the 7 were free from worms, intestinal or other toxæmia, pyorrhea alveolaris, tuberculosis or other intercurrent disease.

(6) Both eyes were invariably affected. Itching was more or less constant, being sometimes intense. Photophobia was nearly always present, sometimes extreme, so that the patient walked with head bent. Cases Nos. II and VI showed great watering and sneezing. A tendency to sneezing was present in most cases.

(7) The palpebral type was less common, only 2 out of the 7 showing the typical granules. The limbal type was more frequent. In 2 cases both were found. In 2 cases of this series, as well as in a few of the subsequent cases, there was a slight dusky discoloration in the area of the inter-palpebral fissure similar to that in cases of deficiency diseases (xerosis of the conjunctiva or early keratomalacia). Perhaps these patients had an early symptom of this condition along with vernal catarrh.

(8) In all except Case No. IV there was an abnormal and often unhealthy condition of the nose and throat. Case No. VI gave a history of frequent colds also. Smell was unaffected.

(9) A smear of the sticky thread-like conjunctival discharge or of a scraping from the tarsal surface stained with Leishman's stain showed numerous eosinophiles. In fact these cases were diagnosed on this fact, and other cases with symptoms similar to these, but without eosinophiles in the discharge, have been left out of account. We are now studying such cases also as being probably transitional or early stages of the same disease as mentioned by Sobhey Bey of Egypt (3).

(10) Blood examination showed a distinct eosinophilia. There was no leucocytosis and no increase in the coagulation time of the blood. One case showed a leucopænia, and lymphocytosis was observed in some.

(11) None had any corneal or other complication and no serious refractive error.

(12) Bacteriological examination by smears and cultures showed no pathogenic organisms—*B. xerosis* and *Micrococcus epidermidis albus* were sometimes found.

(13) *Treatment*.—Was fairly effective during the time the cases stayed here.

The following measures were employed.

Local—(a) Protective glare glasses—this relieved the photophobia, the blepharospasm and sneezing to some extent. Beyer (4) says that exclusion of air has a salutary effect. Neither the partial exclusion by these glasses nor the complete exclusion by pad and bandage or by a modified Buller-shield seemed to have any additional value.

(b) Every eye was treated with boric lotion wash twice daily with instillations of adrenalin drops, and calomel dusting and gentle massage at bed time with a little yellow ointment (Ung. Hyd. Oxidi Flava $\frac{1}{2}$ per cent) put in. When discharge was copious the lids were everted and the conjunctiva swabbed with silver nitrate solution (5 grs. to 1 oz.), and washed with saline, and argyrol solution (5 per cent) instilled. When itching was great and in the tarsal cases Knapp's roller forceps was used with amelioration of symptoms. In Case No. VI, who has been under observation and treatment for several years, repeated application of roller forceps, shaving off of the tarsus with the scalpel, applications of strong silver nitrate solution up to 60 grs. to 1 oz., repeated application of carbon dioxide snow (some of these measures under chloroform), copper sulphate application, prolonged use of Zambelletti's unguentum cupro-argenti, instillations of fibrolysin solution, dionine drops, sub-conjunctival saline injections were all employed at one stage or another. Though symptoms would appear abated a little, yet my feeling has been that the treatment had no great influence on the course of the disease.

Though application of silver nitrate dilute solution, as also acetic acid solution, relieved the itching and discharge in some patients, yet its indiscriminate use in others produced a worse condition than before, adding to the specific conjunctivitis a chemical irritative inflammation. On the whole, silver nitrate appears unsuitable to the cases we meet with here.

General—(a) *Dietetic*.—The patients were put on a vitamine-rich diet, but it seemed to have no visible effect. Similarly cod liver oil and in one case sodium morrhuate injections were of no value.

(b) *Medicinal and Operative*.—All these 7 cases were put on a mixture containing calcium

lactate in doses of 10 to 15 grs., three times a day. It is said (5) that calcium deficiency is probably a cause. In addition they were given injections of nuclein twice daily; this was with the idea of producing a leucocytosis and changing the abnormal picture of the white corpuscular element of the blood which is an outstanding phenomenon. Great improvement was observed in every one of these patients, and I am inclined to credit the calcium and nuclein treatment with this good result.

(c) Case No. VI was treated for some time with hay fever vaccine, as well as with an auto-vaccine prepared from the nasal cavity.

Treatment of Nose and Throat.—All cases except Case No. IV were treated with swabbing the throat with protargol solution daily. In cases of unhealthy noses a menthol and eucalyptus ointment (menthol gr. v. oil of eucalyptus m.x., vaseline 1 oz.) was snuffed into the nose twice daily. Brinton (6) of Johannesburg considers that follicular tonsillitis or other trouble of that organ is the cause of vernal catarrh in South Africa and that cure follows enucleation of the tonsils. Though symptoms were ameliorated by medicating the nose and throat along with other measures, we did not find any great improvement in two other cases (not in this series) who had their tonsils taken out.

The constantly bilateral nature of the affection, the blood changes, the general lymphatic enlargements observed by some writers (Ticho (7)) indicate that this disease is probably an ocular manifestation of a constitutional disturbance. Some think that calcium metabolism is at fault; while others consider it a condition of vagotony (8). The considerable preponderance of young adolescent males (90 per cent, Bail (9) 92.31 per cent. Ticho (7) may indicate an imbalance of the internal secretions at least as a predisposing factor. Rizzo has described abnormal secondary sexual characters in practically all of his eleven cases. Except in Case No. 11 of our series where they were ill-developed there was no abnormality.

If one may be permitted to conjecture, perhaps the key to the proper understanding of this disease lies in a complete knowledge of the origin, function and fate of the eosinophile leucocyte in the blood. The well known textbooks are silent on the point. Bond (10) says that "eosinophiles seem to be a distinct variety or race of leucocytes and not merely polymorphonuclears which have acquired eosin-staining granules as the result of feeding on hæmoglobin," and concludes that "the life-history of the eosinophile cell and its relation to other varieties of leucocytes requires further study."

Seventeen years ago, inspired by a paper by Sir Pardey Lukis (then Colonel Lukis, Principal of the Calcutta Medical College) on the blood condition of Bengalee students of his institution,

and under the guidance of Professor Colonel Donovan of Madras, I studied the leucocytic distribution in nearly 100 Madras Medical College students and to my surprise found that several students had an eosinophilia of 10, 15, or 20 per

cent (in 2 cases more than 50 per cent) but were free from the usual causes of eosinophilia and apparently perfectly healthy. Further investigation was not made and unfortunately I have lost these records.

Tabulated Statement of Observations on 7 Cases of Vernal Catarrh of Conjunctiva.

No.	Race, sex, age.	Occupation.	History, etc.	Symptoms and appearances.	Blood.	Conjunctival discharge.	Nose and throat.	General health.
I.	A. R. Hindu, male, 16	Student	Duration 3 months. After a short malarial attack, eyes became red and watering along with sneezing attacks.	Both eyes slightly red and watery. Great photophobia and much sneezing. Great itching, particularly at inner canthi. Upper palpebral conjunctiva congested. Pale red gelatinous elevated irregular growth encroaching on cornea irregularly.	Total count R. B. C. 7,920,000 W. B. C. 3,500 Differential. Poly. 49.0 Lymph. 44.0 Eosino. 16.0 Later after treatment. Poly. 62.0 Mono. 4.0 Eosino. 14.0 Lymph. 20.0 Coagulation time 4 mins.	Epithelial cells and leucocytes majority being eosinophiles B. Xcr + +	Nose big and nostrils too roomy. Deviated septum to right. R. inf. tub. hypertrophied. Obstructed breathing R. side. Tonsils enlarged. Granular relaxed pharynx.	Good. Delicate-looking. Urine, Faeces B.P., etc., etc., normal. Sexual development normal.
II.	N. I. Hindu, male, 20	Agriculturist.	Duration 3 years. Aggravated during summer months but better after rains. Treated in various places by regular practitioners and quacks.	Both eyes affected. Redness and watering. Very great photophobia and itching. Blepharitis and sneezing marked. Head bent and forehead furrowed and pseudoptosis. Palpebral conjunctiva congested and velvety; upper tarsal conjunctiva has the typical flattened "cobble-stone" granules. Prominent, gelatinous, raised irregular encroaching, limbal appearance.	R. B. C. 6,200,000 W. B. C. 5,600 Poly. 46.6 Lymph. 28.4 Eosino. 25.0 Later. Poly. 46.0 Lymph. 40.0 Eosino. 12.0 Coagulation time 4.5 mins.	Eosinophiles + + +	Chronic granular pharyngitis and chronic follicular tonsilitis present. L. inf. turbinate enlarged and breathing difficult in L. nar's.	Fairly good. Secondary sexual characters not well developed.
III.	R., Hindu, male, 14	Student	Duration 8 months. Now and then aggravated.	Both eyes affected. Burning, itching and slightly watering. Slight redness. Tarsal conjunctiva shows flat topped granulations of different sizes. Limbal gelatinous growth marked on the 2 sides and absent above and slight below.	Poly. 44.0 Lymph. 40.0 Eosino. 16.0 Later. Poly. 52.9 Lymph. 18.0 Mono. 4.6 Eosino. 16.0 Coagulation time 2.4 mins.	Eosinophiles + + + B. xerosis + M. albus +	Granular pharynx. Tonsils healthy. Slight septal deviation of nose.	Good.
IV.	A. S., Hindu, male, 15	"	Duration 1 year. Aggravated at times, but symptoms and appearances better with rubbing.	Both eyes affected. Eyes slightly pink and slight watery. Much itchiness. No sneezing. Palpebral conjunctiva normal. Limbal growth moderate. Sclera slightly dusky at interpalpebral area.	Poly. 42.0 Lymph. 41.0 Eosino. 17.0 Coagulation time 4 mins.	Eosinophiles + +	Healthy.	Good.

No.	Race, sex, age.	Occupation.	History, etc.	Symptoms and appearances.	Blood.	Conjunctival discharge.	Nose and throat.	General health.
V.	K. M., Hindu, male, 19	Student	One year's duration. Aggravations now and then. No sneezing.	Both eyes affected. Eyelids heavy and drooping. Eyes watery. Ocular conjunctiva appears dusky and limbal gelatinous appearance prominent. Follicular appearance of pal conj.	Poly. 55'0 Lymph. 35'0 Eosino. 9'0 R. B. C. 51,200,403 W. B. C. 7,760 Coagulation time 3'5 min.	Eosinophiles +++ B. xerosis ++	Slight granules in pharynx. Slight deflection of nasal septum.	Good.
VI.	G. K. R. Hindu, male, 20	"	Duration 10 years. Started with "sore eye." Condition gets worse—usually in summer but also rarely at other times. Treated in various ophthalmic and other hospitals with operation, injection and local applications. Has generally improved in symptoms.	Both eyes affected. Conjunctiva slightly congested. Typical tarsal cobble-stone pavement—Cartilaginous growths present. In other areas follicular. Slight blepharospasm and some photophobia. Sneezing prominent at times.	Poly. 51'0 Eosino. 29'0 Lymph. 29'0 Later. Poly. 57'0 Eosino. 18'3 Lymph. 25'0 Coagulation time 3'4 mins.	Eosinophiles +++	Hypertrophic rhinitis at present. Frequently suffers from colds.	Good.
VII.	A. S., Hindu, male, 17	"	Duration 18 months. Worse in summer. Itching and sneezing at times.	Both eyes affected. Thick limbal greyish growth. Photophobia slight.	Poly. 60'0 Lymph. 22'0 Eosino. 18'0 Coagulation time 4 mins.	Eosinophiles ++	Deviated nasal septum.	Good.

May it be that eosinophilia indicates a metabolic aberration within health limits with a predisposition to vernal catarrh, the exciting causes being climatic, seasonal or otherwise?

CONCLUSIONS.

- (1) Cases of vernal catarrh of the conjunctiva are fairly common in the table-land of Mysore and adjoining parts.
- (2) Adolescent males are most commonly affected—especially in the late summer months. Most of the patients were vegetarian Hindus.
- (3) Caustics and operative treatment seem to do no good, but calcium salts and nuclein had a perceptibly good effect.
- (4) Most of the patients had unhealthy nose and throat conditions, treatment of which seemed to improve the eye condition.

Or all diseases that incapacitate a soldier dysentery is one of the most important. It was a scourge of the ancient armies and proved to

* Published by kind permission of the Director of Medical Services, India.

be the same in the Great War, with this difference that we were much better acquainted with its ætiology and hence were in a better position to prevent and treat it. It has been fully recognised that without the aid of the laboratory the accurate diagnosis of the disease—if not altogether impossible is no easy matter, and the danger of the indiscriminate use of emetine has been fully brought home. In view of these facts an effort was made to correctly classify all cases passing blood and mucus in their stools. The following is a summary of the work carried out from January 1926 to October 1927.

Incidence of Dysentery among British and Indian Troops.—The ubiquitous nature of the disease is well known. We find it prevailing throughout the year to a greater or a lesser degree. The numbers per month are shown on the accompanying chart. It will be observed therefrom that the Indian troops suffered much more than the British, but in both cases a similar seasonal variation is present. From a few cases in the first six months, there is sudden jump in July which reaches its climax in August, and gradually comes down to normal in November.

Laboratory Findings.—As the laboratory results are always judged by the technique employed, the following gives in brief the details of the procedure adopted in dealing with all stools.

1. The stool, after testing the reaction with litmus paper, was examined microscopically for its exudate. From the stool a flake of mucus was picked up on a platinum loop, introduced into a test tube of sterile saline (to remove any extraneous bacteria, etc.), and plated out on bile-salt-litmus-lactose-agar. After 24 hours' incubation, suitable colonies were picked out and tested for motility by a hanging drop preparation; on their proving non-motile they were transferred

to glucose and mannite sugar media containing Andrade's indicator. The organisms fermenting glucose or glucose and mannite were further inoculated from these tubes into lactose, dulcitol, and peptone tubes (for the indol reaction). Finally, serological reactions were used to confirm the result of the bio-chemical reactions.

2. No diagnosis of amœbic dysentery was based on exudate alone, and, if in addition to the pathogenic amœbæ, a bacillary exudate was present, an attempt was always made to isolate the causative bacilli by the cultural methods detailed above. The presence of a scanty exudate, consisting of a few lymphocytes and eosinophile cells, sometimes with Charcot-Leyden crystals, was an indication for a prolonged search, hence attention was always concentrated in such cases on finding the *Entamœba histolytica*.

Adopting the above methods we obtained the following results:—

Total number of cases with mucus or blood and mucus	404
Number of cases from which <i>B. dysenteriae</i> were isolated	178
Number of cases in which <i>Entamœba histolytica</i> was found	43
Number of cases showing a bacillary exudate, but pathogenic amœbæ or bacilli were not found	101
Number of cases showing an indefinite exudate only	82

Taking the above figures into consideration, and working out percentages, we find that of all cases showing mucus or blood and mucus

69.06 per cent. were bacillary (including those from which *B. dysenteriae* were isolated and those showing bacillary exudate).

10.64 per cent were amœbic.

20.3 per cent were indefinite (no specific exudate, no pathogenic amœbic or dysentery group of organisms having been detected).

Of the 279 "bacillary" cases noted above we find that the *B. dysenteriae* group could be isolated from over 63.8 per cent of cases, or taking the indefinite cases into consideration in 49.3 per cent.

The following numbers show the variety of the organisms encountered.

Total number of cases from which successful isolation was made	178
Number of cases showing <i>B. Flexner</i> group	147
Number of cases showing <i>B. Shiga</i>	22
Number of cases showing <i>B. Schmitz</i>	9

Serological identification could only be carried out in a few cases of the Flexner group. The inagglutinability of the recently isolated cultures of these organisms is too well known to be discussed here. At first an attempt was made at sub-culturing, but this had to be abandoned to save confusion reigning in the laboratory and reports getting into arrears, especially in the "dysentery season" when the number of stools dealt with in a day sometimes exceeded forty.

It will be observed that the percentage of Shiga infections is fortunately small, and that the majority of the bacillary infections are due to the members of the Flexner group. It would have been most interesting to work out the actual strains, their toxicities as well as their relation to the sera from the cases themselves, but owing to lack of facilities and the rush of work this could not be carried out fully.

Seventy-nine of the cultures isolated locally were put up against polyvalent high titre serum obtained from the Central Research Institute, Kasauli, out of which fifty were agglutinated (without sub-culturing repeatedly). This 63 per cent. positive agglutination proves the futility of the method advocated by some workers of classifying the organisms after picking up colonies from the plates and doing direct agglutination. A high titre serum was also produced from two typical local strains by injections of rabbits as described by Manson-Bahr and Perry (*Practice of Medicine in the Tropics* Byam and Archibald. Vol. II, p. 1110). These sera agglutinated their respective strains up to a dilution of 1:2,500, and by putting them up against the standard Oxford emulsions of the various strains of *B. Flexner* group and doing the "absorption" test it was found that the original cultures belonged to "V" strain. Twenty out of the twenty-five cultures isolated locally were agglutinated by this serum. It is highly probable that the V strain is the leading one in Secunderabad amongst the Flexner group of organisms.

It need hardly be added that no organisms were diagnosed as *B. Shiga* unless they were agglutinated by the high titre Shiga serum.

The Source of Infection.—Whatever the vector of the causative organisms, the main source of infection is undoubtedly the "carrier," whose distribution must be far and wide in this cantonment. The laboratory examination for carriers is not as much of a success as one would like it to be. Our routine has been to examine three normal stools for entamoebæ, cysts, ova, etc., and three after a saline purge for bacillary dysentery. For the latter purpose the stools are plated out and dealt with as described in the first part of this paper. That this dangerous source of infection exists in the civil population will be evident from the following data:—

Total number of menials examined .. 838
Total number found positive for *B.*
Flexner .. 28 or 3.4 per cent.

Total number in which *Entamoeba histolytica* cysts were found .. 28 or 3.4 per cent.

It may be interesting to note here that *B. typhosus* was isolated from five of these cases.

The number of positive results, small though they are, show the importance of the examination of menials concerned in the handling of food: or, putting it in another way, we might say—surrounded as the troops are on all sides by the enemy (carriers), the importance of

eliminating the same from within the lines is a preventive measure of the first order.

SOME INTERESTING OBSERVATIONS.

I. *Reaction of Dysenteric Stools.*—One hundred and fifty-nine stools brought to the laboratory with blood and mucus from which *B. dysenteriae* group were isolated are especially chosen for discussion here. It was found that 144 or 90.6 per cent of these were alkaline to litmus and the rest, i.e., 9.4 per cent gave an acid reaction. The latter phenomenon was noted specially in stools which had been despatched to the laboratory after a delay of two or more hours.

The number of our amœbic cases is too small to give any definite opinion as regards their reactions, but in all the six cases of mixed infection (see below) the reaction was alkaline, so that the alkaline reaction alone would not be sufficient to eliminate the presence of pathogenic amœbæ.

2. *Exudate.*—Out of the 178 cases from which specific bacilli were isolated 129 or 72.5 per cent showed a definite bacillary exudate at the first examination, while a few exhibited it at a later date. The rest, i.e., showing no bacillary exudate, were of a milder nature containing a large amount of mucus but little blood, all being due to the Flexner group of organisms.

As has been pointed out before, no diagnostic importance was attached to "amœbic" exudate or Charcot-Leyden crystals, their presence being interpreted as a hint for prolonged search.

3. *Mixed infections* were encountered in six cases during the whole year. It may be coincidence but all six cases began as bacillary dysentery and the pathogenic amœbæ were found on or after the fourth day.

4. *The Importance of Time in Examination of Specimens.*—That time is a great factor in successful isolation is shown by the following facts:—

Total number of stools from the British Military Hospital situated quite adjacent to the laboratory ..	165
The causative bacilli were cultivated from ..	76 or 46 per cent.
The total number of stools received from the Indian Military Hospital, a mile and a half away ..	252
Total number from which <i>B. dysenteriae</i> were cultivated ..	87 or 34.5 per cent.

CONCLUSIONS.

1. From the above we can safely conclude that bacillary dysentery is a far more prevalent disease than the amœbic type. The medical officer who uses emetine or allied drugs without laboratory diagnosis would be wrong in nearly nine cases out of ten.

2. It has been possible to cultivate the causative organisms from nearly fifty per cent of cases, but with the proper co-operation of the medical officers it would be possible to obtain much better results.

3. The carrier problem, here as elsewhere, is very important in Secunderabad among the civilian population.

Finally, we would like to say that the inspiration to classify the dysentery cases scientifically was mainly derived from the paper on "Important features in the correct diagnosis of Dysentery in India" by Major J. A. Manifold, D.S.O., R.A.M.C., and our technique as detailed above is identical with the one described by him.

A Mirror of Hospital Practice.

A CASE OF HYDATID CYST OF THE LIVER.

By W. L. HARNETT, M.A., M.B., F.R.C.S. (Eng.),
LIEUT.-COL., I.M.S.,

*Officiating Professor of Surgery, Medical College,
Calcutta.*

RAM CHAND MISRA, Hindu, aged 8, was admitted to the Medical College Hospital, Calcutta, on 3rd August, 1927. His home was in the Mozufferpur district of Bihar and there was nothing of importance in the previous history. He stated that his parents had dogs living in the house, but no history of any close association with them could be elicited. The history given was that one year ago a swelling had been noticed in the epigastrium. It was about 1 inch in diameter when first noticed, hard, rounded and painless. It had gradually increased in size and become slightly tender. Except for an occasional attack of vomiting and one attack of diarrhoea, there had been no symptoms. He had had no fever during this period.

The boy was well nourished and of healthy appearance, the temperature and pulse were normal and the tongue was clean. In the epigastrium was a globular swelling about 3 in. by 2½ in., it was smooth and of regular outline on palpation, fluctuating and moving freely with respiration. It extended downwards about four fingers' breadth and the upper margin could not be defined. There was no pulsation and no hydatid fremitus. It was approximately on the middle line, extending rather more towards the right and the liver edge was barely palpable beyond the tumour. On percussion the tumour was dull, the dulness being continuous with the liver dulness, and there was no increase of liver dulness in the upward direction. The thoracic organs were normal, no other tumour could be palpated in the abdomen and there were no enlarged glands any where. The urine contained no abnormal constituent. The stools contained ova of *Ascaris* and of *Trichuris*, but no other parasites and no occult blood. The blood count was—

Total white cells	14,700 per cmm.
Polymorphonuclears	.. 51 per cent.
Lymphocytes	.. 24 per cent.
Large mononuclears	.. 2 per cent.
Eosinophils	.. 13 per cent.

An x-ray examination after a barium meal showed the stomach distorted into a curved form with concavity upwards, from which the existence of a tumour pressing down on to it could be inferred. The liver moved freely and no enlargement could be detected with certainty. The emptying time of the stomach was normal and the 6-hour and 24-hour radiograms showed nothing noteworthy.

From the physical signs it was plain that the patient had a cyst in the left lobe of the liver and the diagnosis lay between amoebic abscess, hydatid cyst, cavernous angioma and a tumour undergoing degeneration. The latter appeared incompatible with the good general condition of the boy, and a cavernous angioma is usually a pulsating tumour. The absence of fever is not sufficient to negative liver abscess, especially as there was a well marked leucocytosis, but a liver abscess which has reached the stage of protruding through the abdominal wall is always adherent and fixed and has the vague outline of an inflammatory swelling shading off into normal tissues. The diagnosis of hydatid cyst appeared then the most probable. The eosinophilia would have been valuable confirmatory evidence had it not been for the presence of ova of *Ascaris* in the stools. There was no history of attacks of urticaria and no hydatid fluid was available with which to perform a complement fixation test.

After the removal of the round worms in the usual manner, operation was performed on 31st August, 1927. The abdomen was opened by a right paramedian incision above the umbilicus. A tense rounded tumour, of a pale pink colour, which appeared to protrude through the gastro-hepatic omentum with the stomach wrapped round its lower border came into view. The tumour occupied the whole of the left lobe of the liver, which was converted into a cyst, with the exception of a narrow fringe of liver substance on the lower segment of the cyst. The right lobe of the liver was unaffected. After packing off the neighbouring viscera, the cyst was aspirated and 280 c.c. of clear colourless fluid was drawn off. The fluid contained innumerable solid specks, which on microscopic examination proved to be masses of scolices. An incision was then made into the liver substance and a large cavity was opened. Lying free in this was the true cyst wall, a friable white membrane looking like boiled egg albumin. By careful separation with the finger this was manipulated out of the wound and removed practically entire. Two or three daughter cysts were found floating free in the cavity. The cavity in the liver was partly sutured and a Carrel's tube placed in position for continuous irrigation. The progress of the case was uninterrupted for three weeks, by which time the wound was healed except for a small sinus. A rise of temperature and some abdominal pain then necessitated the reopening of the sinus and the evacuation of a collection of bile-stained mucus in the cavity, which was found to be still

of considerable size. Free drainage and continuous irrigation with E. C. lotion brought the temperature down rapidly and the cavity is at the time of writing nearly filled up. The figure shows a section of the cyst wall in which the endocyst with a "brood capsule" of scolices is well seen.

Hydatid disease is not common in India, presumably because there is not that close association between dogs and human beings which obtains in sheep raising countries, such as Australia and New Zealand, where the disease is so common that 12 to 15 per cent. of the annual death-rate is due to this cause. The *Tania echinococcus* is parasitic only in the dog, wolf and jackal, the dejecta of these animals soil grass and vegetable matter, by the ingestion of which the ova pass into the bodies of sheep and cattle, in which the cysticercus stage is passed. The infection is transferred back by the dog eating contaminated offal of sheep. Man can only act as the host of the cysticercus stage and the infection is usually conveyed by the contamination of drinking water with ova-containing faeces, but it may also be conveyed by too close association with infected dogs, allowing them to lick the hands or face; as probably happened in the present case.

The technique of the surgical treatment of these cases has been much improved by the method of Désé, which consists in the injection of 1 per cent. formalin into the cyst after aspiration, to destroy the endocyst with its brood capsules. The cyst is then removed and the liver sewn up without drainage. This method is applicable to all cases in which there is no suppuration, provided that an effusion of bile is not already present. Such cases should be drained, as the bile is already infected. Under this technique 75 per cent. of cases heal aseptically and in the remainder a septic effusion occurs and the wound has to be reopened, as in the present case. The high leucocytosis in this case suggested that infection was commencing and

that drainage with continuous irrigation might lead to quicker healing.

A CASE OF PROBABLE DERMAL LEISHMANIASIS.

By AMULYA KUMAR BHATTACHARYYA, L.M.P.,
Medical Officer, Dalgram Dispensary, Tushbhandar,
Rangpur.

SERATULLA, aged about 35 years, Mahomedan male, consulted me on the 3rd March 1927 for 'dermatitis exfoliata,' the duration of the disease being about two years. There was no history of syphilis or of any hereditary disease. He had not suffered from prolonged fever, and there was no enlargement of the spleen. Both the upper and lower extremities were extensively affected, but the trunk was almost free. The scalp was also affected.

He was put on to Fowler's solution orally, and ichthyol and chaulmoogra oil for external application. Injections, each of $\frac{1}{2}$ gr. of iodine, were also given twice a week. After a month's treatment there was no appreciable change in his condition. At this stage my attention was drawn to the case of 'dermatitis exfoliata' cured by injections of urea-stibamine, reported by Dr. Norrie in the *Indian Medical Gazette* for March, 1927, p. 142; and to an article on dermal leishmanoid by Dr. B. M. Das Gupta in the April 1927 number of the same journal, p. 199.

I accordingly changed the treatment, and from the 19th April 1927 commenced intravenous injections of a 2 per cent. solution of sodium antimony tartrate, the initial dose being 2 c. c. Up to the date of writing (25th July 1927) the patient has in all received 8 injections, the largest dose being 4 c. c. The patches have completely disappeared, with the exception of a very few on the thigh, and his skin has resumed its normal appearance.

The case could not be examined microscopically or serologically; but, considering the immediate and striking effect of the antimony injections on the disease, it would appear that the condition present was one of 'dermal leishmanoid.'

CONJUNCTIVAL CONGESTION AFTER UREA-STIBAMINE INJECTION.

By NAGENDRA NATH ROY, B.Sc., M.B.,
Sohagpur, P. O. Belkuch, Patna District.

NASERALI MOLLA, a Mahomedan youth, about 18 years old, was receiving bi-weekly injections of urea-stibamine from me for treatment of his kala-azar from the 29th May 1927, with favourable results. A curious feature of the case, however, is that five minutes after each injection both his conjunctivæ become extremely red and congested, and this condition lasts for about two hours. The initial dose of urea-stibamine was 0.05 gm., gradually rising to 0.20 gm. The acute congestion of the conjunctivæ is accompanied by fits of sneezing.

During the past three years, I have treated 175 cases of kala-azar with various compounds of antimony, but this is the only case which I have seen of its type. The condition was not accompanied by coughing, vomiting, dyspnoea, urticaria, itching, oedema or collapse.

A CASE OF CEREBRAL MALARIA.

By J. F. HENRIQUES, I.M. & S., B.M.S.,
Officer i/c West Hospital, Rajkot.

A HINDU girl, aged 14 years, was first seen by me on the 8th September 1927, with a temperature of 105°F., a pulse of 160, and in an unconscious state. I suspected cerebral malaria, but first took a blood film in order to make certain of the diagnosis, for the abdomen was markedly retracted like that in cerebrospinal meningitis, and her condition was very serious. Before leaving the house, and after taking the blood film, I gave her an intramuscular injection of gr. vii of quinine.

Two hours later, as sub-tertian parasites had been found in the film, and the diagnosis of malaria was thus confirmed, I visited the patient again, and administered gr. vii of quinine intravenously, with m.x. of adrenalin chloride solution. The temperature at the time was 104.5°F.

This was followed by profuse perspiration and the temperature dropped to 102°F. at 7 p.m. the same evening, but the patient was still unconscious. Early next morning, she was conscious, with a temperature of 101°F. I gave another intramuscular injection of gr. vii of quinine.

On the 10th, I administered oral quinine, as the patient much objected to the intramuscular injections, which were painful, and also gave plasmochin orally. In the evening the temperature rose to 102°F. and she again became unconscious. Owing to her tossing about, it was not possible to give an intravenous injection, so a further dose of gr. vii of quinine was given intramuscularly. The next day, she was semi-delirious, but able to swallow medicine, and quinine was given orally. Finally she made a complete recovery on quinine medication.

The interesting features of the case were:—

(1) On the day prior to my seeing the patient, she had had fever of remittent type with rigors for four days, and the temperature had never fallen below 101°F. The doctor then in charge had given instructions that quinine was to be given when the temperature fell below 100°F.; but this never happened, so the patient went on to develop cerebral malaria. Many medical men still refuse to give quinine to malarial patients whilst the temperature is elevated, despite the teaching of text-books to the contrary, and the old-fashioned and erroneous view that quinine should not be given during the febrile phase still persists. The golden rule should be to give quinine as soon as the bowels have been opened, or to administer it alternately with an alkaline mixture.

(2) Secondly, the large amounts of quinine which had to be given to this patient of 14 years of age to get the fever under control; viz., 1st day gr. 7 intramuscularly and gr. 7 intravenously; 2nd day, gr. 7 intramuscularly; 3rd day 7 gr. intramuscularly, two tablets of plasmochin, and 25 grs. of quinine by the mouth; 4th day, gr. 5 of quinine intravenously, and three plasmochin tablets; 5th day, quinine gr. 25 in solution orally, and three tablets of plasmochin; 6th day, the same as on the 5th day. Her temperature did not reach normal until the 6th day.

I am much indebted to Colonel Tyrell, I.M.S., for the suggestion to give a first intravenous injection of quinine and then to follow it up by an intramuscular injection of quinine; the idea being in the first instance to secure the maximal immediate action of the drug, thereafter to be reinforced by slower absorption from the intramuscular injection.

CASES OF MALARIA IN A FAMILY.

By Capt. S. B. MUKERJI, M.B.,
Civil Medical Officer, Kurseong.

A HINDU male child living here, who had been exposed to infection in the foothills to both malaria and kala-azar, developed irregular inter-mittent fever, with loss of appetite, irregularity of the bowels, anaemia and emaciation. The liver and spleen became enlarged, the latter reaching to the umbilicus. The aldehyde test carried out by my assistant, Dr. B. K. Biswas, was reported to be partially positive.

After four injections of urea-stibamine, the patient's condition was not improved. Blood films, sent to Calcutta, did not show any malaria parasites, but the leucocyte count was suggestive of that disease. Quinine had been given rather irregularly and without effect, but on the strength of the Calcutta report, quinine was given intramuscularly, followed by regular doses of quinine by the mouth. The child made a rapid recovery.

The parents also went down with fever. In the case of the mother, no parasites could be found in blood films, and the aldehyde reaction was partially positive. By way of comparison, the serum of a patient suffering from kala-azar, and who had been under successful treatment with urea-stibamine for some time, was taken; this gave a positive aldehyde test, though only after the lapse of some time.

The father went down with fever five weeks after the child, and in his blood film sub-tertian malarial parasites were found. The aldehyde test was not carried out in his case.

As a contrast to the above cases one may mention that of a child of about 3 years of age, who had been treated for irregular fever with enlargement of the liver and spleen, and advanced stomatitis. He had had prolonged treatment with quinine in his village before I saw him. I had no urea-stibamine available at the time, so put him at once on to injections of sodium

antimony tartrate. He did so well that, when the urea-stibamine ordered arrived, the parents refused to pay for it, preferring the cheaper sodium antimony tartrate. The injections were given by Dr. S. K. Biswas.

Points in connection with such cases are (1) what is the diagnostic value of a partially positive aldehyde test? (2) What caused the entire absence of malarial parasites in these febrile, and non-quininised cases, which were certainly cases of malaria? (3) Why did the mother and child show partially positive aldehyde tests?

A CASE OF RETROGRADE STRANGULATED HERNIA.

By K. M. NAYAK, L.M. & S.,
Assistant District Medical Officer, North Arcot,
Vellore.

THE following case seems to me to be worthy of record, owing to the rarity of the condition described, and it may be of interest to those who

hours to bring him in, and he was first seen at 8 a.m. on the 1st October, 1927.

His condition on admission was very bad. Pain in the tumour had practically ceased; the temperature was subnormal; the pulse slow, thready, and almost impalpable. In other words, he was in a severely toxic state and completely collapsed, and the first question which I had to answer was whether he would stand the shock of an operation.

As operation, however, was the only chance of saving life, continuous hot saline was administered *per rectum* from 8 a.m. till 10 a.m., when the patient was placed on the operating table, and injections of adrenalin and pituitrin given. When placed on the table he was packed in warm blankets and hot water bottles, and the apparatus for intravenous saline was got ready. The patient stood the actual operation itself apparently well, though it lasted nearly three-quarters of an hour.

I was under the impression that I was going

are called upon to carry out emergency operations in India.

The patient, a man aged about 55 years, was admitted to the Pentland Hospital with strangulated hernia on the morning of the 1st October, 1927. The hernia was of about the size of a coconut, and had suddenly become strangulated about 10 p.m. the previous night. As the patient lived some 10 miles from the hospital, it took ten

to deal with an ordinary "common or garden" type of strangulated inguinal hernia. The seat of the strangulation was at the neck of the hernial sac, as usual, but the strangulated coil was not in the sac at all, but in the abdomen. This is a very rare type of strangulated hernia.

On opening the sac two nearly normal loops of small intestine were found,—a W-shaped hernia. In addition to this, the sac contained the

cæcum, the appendix, the end of the ileum, and the previously mentioned loops of ileum. These were all in a healthy condition, whilst the sac contained a lemon-yellow fluid, apparently due to a condition of hydrocele. The tumour was about the size of a cocoanut.

On drawing down the intra-abdominal loop of small intestine, an intermediate portion, about six feet in length, blackish, and in a condition of gangrene, was brought into view. To carry out a resection and an end-to-end anastomosis was impossible, owing to the critical state of the patient, for his pulse was failing and he was gasping for breath. The gut was returned to the abdomen; the incision sutured, and a pint of saline with adrenalin run into the median cephalic vein. The patient died about half an hour after he had been taken back to the ward.

Although very uncommon, retrograde strangulation is an extremely grave condition, and the lesson which such cases teaches is this; that the contents of a hernial sac—no matter how satisfactory their condition may appear to be—should never be returned to the abdominal cavity without first drawing down a sufficient length of the ileum to ensure that retrograde strangulation is not present. In other words, a hernia should not be reduced until the conditions present have been very thoroughly understood and appreciated.

A rough sketch of the conditions present in this case is reproduced with this article.

AN UNUSUAL FOREIGN BODY IN THE PLEURAL CAVITY.

By A. G. PEREIRA, L.M.S.,

Assistant Surgeon, Municipal Hospital, Pollachi.

A SHEPHERD boy, Arunchellam by name, set out one day to procure fodder for his sheep. He climbed a tree to the height of about 20 feet, and was plucking twigs with a billhook tied to a pole, when he fell and a broken end of a dried-up branch of the tree penetrated the left side of his chest a little below the armpit, fracturing and splintering the 3rd and 4th left ribs. He was lying unconscious when some passers-by picked him up and brought him to hospital the next morning after the accident, apparently some 16 hours after it had occurred. The sub-assistant surgeon who was on duty at the time cleaned up the wound and applied a dressing.

When I saw him the next morning, the dressing was soaked with foul-smelling pus; his temperature was 104°F., and respirations 80 per minute. Operation was carried out immediately. The splintered rib fragments were snipped off; a large drainage tube inserted, and retaining sutures put in.

After operation the patient's temperature dropped to 100°F., and for some days continued between 100° and 102°F., but his progress was unsatisfactory. Finally, on the 16th day after the accident, the pleural cavity was explored,

whereupon a fairly big, rough, loose body was felt inside the pleural cavity. He was now operated upon again, and an irregular splinter of wood measuring 2½" long by 1½" wide was removed from inside the chest.

Subsequent to this the patient's progress was uneventful. The pleural cavity was irrigated daily for some days with an iodine solution and afterwards with a perchloride lotion. He was discharged cured on the 17th day after the second operation.

A CASE OF MALIGNANT MALARIA.

By N. CHATTERJEE, M.B.,

Domjurh, Howrah District.

BIJUPENDRA NATH CHUKRAVARTI, a student, was suffering from fever, and I was called in to see him on the second day of illness. I found him with a temperature of 104.5°F., intense headache, pains all over the body, nausea and bilious vomiting, and constipation. A blood film was immediately taken—as the condition suggested malignant tertian malaria—quinine bihydrochloride gr. x. at once given by the mouth in solution, and symptomatic measures adopted for the fever. But I could find no malaria parasites in the films, and the total leucocyte count was 6,000 per c.mm.

The next day his condition was worse, with severe headache, marked tympanites, pulse 160 per minute, and respirations 45. The patient was delirious, and lumbar puncture was carried out; but examination of the fluid excluded cerebro-spinal meningitis. During the night, when I was again called in, the rectal temperature rose to 105°F., and the axillary to 103.5°F., the pulse being about 170 per minute, and the heart sounds almost inaudible.

On the next day, I explained the gravity of the situation to the patient's relatives, and despite my inability to find malaria parasites in the blood films taken, decided to treat the case as one of malignant malaria. Adrenalin, ½ c.c. of 1:1,000 solution was given hypodermically, and strophanthin, gr. 1/500th intravenously; and this was followed up by an intravenous injection of gr. 4½ of quinine hydrobromide in 20 c.c. of normal saline. The rectal temperature subsequently rose to 109°F. and the axillary to 107°, but the patient was treated with ice packs and iced saline per rectum continuously.

On the fifth day of illness the patient was definitely better, with an oral temperature of only 103.5°F., and conscious. I now found scanty ring forms of *Plasmodium falciparum* in blood films taken that morning. I therefore continued the administration of quinine intravenously, giving another gr. 4½ that morning. On the sixth day the patient was convalescent with a normal temperature, and on administration of quinine by the mouth made an uninterrupted recovery.

My reasons for reporting this case are as follows:—

(1) Many of my brother medical practitioners rely on the effect of three consecutive intramuscular injections of quinine, or of examination of a single blood film, to exclude the diagnosis of malaria. Neither method is infallible.

(2) The intravenous method of administration of quinine is the one which is most appropriate for these very severe and comatose cases. Adrenalin, given previously, wards off all dangers of cardiac failure.

(3) A negative blood finding in suspected cases of malignant tertian malaria is of no value; there are a number of such cases where, for some reason or another, parasites are not found in blood films from the peripheral blood-stream. In such cases the medical attendant should treat the patient as if he were suffering from malignant tertian malaria, whilst daily examination of blood films may finally prove the tentative diagnosis.

A CASE OF ANEURYSM OF THE COMMON CAROTID ARTERY AT AN EARLY AGE.

By P. A. G. MUDALIAR, L.M.P.,

Sub-Assistant Surgeon, Civil Hospital, Syriam.

A BURMAN aged 19 years was admitted to the Syriam Hospital on the 14th May, 1924, for the treatment of a swelling on the right side of the neck. It had commenced as a small swelling 5 months previously, gradually increasing to its present size, and during the last 15 days had been causing intolerable pain. He had sought admission as a last resort to have it opened, thinking it to be an abscess. The patient gave a history of a sore on the penis two years previously. There was no history of injury.

On examination there was a tumour on the right side of the neck about the size of a hen's egg just below the angle of the jaw. The swelling was tense and cystic and lay under cover of the sterno-mastoid muscle. The presence of well marked expansile pulsation over the whole tumour was sufficient for me to make a diagnosis of carotid aneurysm. The glands in the groin and the epitrochlear glands were large and shotty. Beyond a small scar on the penis, there were no signs of syphilis.

At operation the tumour was found to be a sacculated aneurysm, arising at the bifurcation of the right common carotid, the origin of both internal and external carotid arteries being involved. The tumour was pressing backwards against the transverse processes of the cervical vertebrae. The vessels were ligatured above and below, and the tumour removed by dissection. The wound healed by first intention and the patient was discharged free from pain.

This case would appear worthy of record on account of the early age at which the aneurysm occurred, and also on account of the shortness of

the period between the infection with syphilis and the development of the lesion.

I am indebted to Dr. R. H. Liscombe, M.B., B.S., D.P.H. (Lond.), Superintendent of the Syriam Hospital, for his kind permission in allowing me to publish this case.

DYSPHAGIA AS A COMPLICATION OF MALARIA.

By Capt. C. C. DAS GUPTA, M.B.,

Chief Medical Officer, Gopalpur Tea Estate, P. O. Gopalbagan, Jalpaiguri.

MRS. H., Hindu female, aged 24 years, 2-para, suffered from incessant fever from the 13th August, 1927, and I was called in to see her on the 16th of that month as her temperature had risen to 105.6°F. that morning. I found her having a rigor and covered with a quilt.

I applied cold sponging to the head, calomel, an alkaline mixture, and quinine hydrobromide, gr. x in a mixture twice daily. She vomited throughout the night, but was much better on the 17th and 18th. On the 19th the temperature again rose to 103.4°F., with incessant vomiting the whole of that night. On the 20th she could not swallow at all. Severe spasm of the throat came on about every five minutes and would last for a few seconds. On arrival that evening I examined the mouth, pharynx and naso-pharynx most carefully, but could find no cause for the very distressing condition. The larynx was clear and she could speak normally. The temperature was 103.4°F. There was no swelling of the neck, but marked tenderness over the lower third of the outer border of the right sterno-mastoid muscle. The chest was clear. During the spasm of the throat she had to be raised in bed, and threw her arms round the attendant to support herself. She appeared to be half choked until the throat had been cleared by spitting. There was, however, no cyanosis.

I at once gave an injection of atropine sulphate, gr. 1/100th, applied hot fomentations and Antiphlogistine over the throat, and gave a gargle containing potassium chlorate and glycothymoline. The next day—21st—she was better, but still unable to swallow even fluids. I gave an injection of atropine, also one of digitalis, and one of quinine. For the throat condition a steam spray with carbolic acid and menthol in it was used, and adrenalin and cocaine in liquid paraffin. The fomentations and Antiphlogistine were continued; an enema given, and rectal feeding instituted.

On the morning of the 22nd the tenderness in the throat had disappeared, but the patient was still unable to swallow. At 4 p.m. the temperature rose to 100°F., and she fainted. When she came round she begged me to discontinue the rectal feeds, owing to their discomfort. At 5 p.m. she could sip water in teaspoonfuls, and that evening was able to take a cup of milk and weak tea. She now made an uneventful recovery.

The patient was an intelligent and well educated female, and, as far as I could make out, not of a neurotic temperament. She had complete dysphagia for three days. Atropine seemed to have been the most active agent in curing this condition, whilst quinine and soamin injections, cured the malaria. It would appear that the incessant vomiting associated with the fever had produced either inflammation or erosion in the œsophagus, leading to the œsophageal spasm and dysphagia.

A CASE OF SUBMAXILLARY CALCULUS.

By M. UMAR,

Offg. Civil Surgeon, Bijnor.

RAM SAROOP, a middle aged patient, came to this hospital and was admitted on the 9th of March, 1927. The submaxillary region of the left side was swollen. In the centre of the swelling was a small ulceration, with pus exuding from it. I probed this and found a hard substance, so naturally concluded that the mandible of that side was necrosed.

I enlarged the wound and put my finger into it, and to my astonishment found a round flat stone, weighing 120 grains, embedded in the substance of the submaxillary gland, oval in shape, with a smooth notch near one pole.

After removal of the calculus the patient made an uneventful recovery and was discharged from hospital cured. I considered removal of the gland unnecessary.

A CASE OF UNUSUAL FOREIGN BODY IN THE ŒSOPHAGUS.

By BABU PRASAD GUPTA, L.M.P.,

Medical Officer, Mallawan Dispensary, Hardoi District.

THE following case of a very unusual foreign body in the œsophagus may be of interest to readers of the *Gazette*.

A fairly well built man aged about 45 years was brought to this dispensary with the history that a *belcha*—(a small mattock or trowel used for digging and up-rooting weeds)—had lodged in his throat. He complained of severe pain in the gullet, could only speak with great difficulty, and could swallow nothing at all. His attendants said that at first the *belcha* was visible from the mouth, but all efforts to extract it had only succeeded in pushing it down further until it had become invisible.

Nothing could be seen or felt through the mouth, but a hard projection could be felt in the neck on the left side. Every effort to extract the implement via the mouth failed. As the

patient was showing signs of impeded respiration, and œdema of the glottis threatened, I put him under chloroform and made an incision about $3\frac{1}{2}$ inches long along the anterior border of the left sterno-mastoid. Having dissected down until I reached the œsophagus, I now tried to push the *belcha* upwards, and to extract it through the mouth with a long forceps, but on account of its tapering upper edge it slipped every time.

I then opened the œsophagus through an incision about $1\frac{1}{2}$ inches long and tried to extract the *belcha* through the wound, but as it was $9\frac{3}{4}$ inches long and $2\frac{1}{2}$ inches broad I was unable to extract it by this route.

Finally, with one finger resting on the *belcha* just above the neck, and the thumb on the opposite side of the neck, I succeeded in gradually dislodging it upwards. Working it steadily and

gradually upwards I finally succeeded in making it visible in the pharynx, but again failed to extract it with forceps. I then inserted two fingers into the mouth and with great difficulty grasped the presenting part of the *belcha* with them through the mouth and finally extracted it. The incision into the œsophagus and the external wound were then sutured.

The wound healed by first intention, and the patient was discharged cured on the ninth day. The *belcha*, on being weighed, was found to weigh 8 ozs.

Whilst he was in hospital, the patient appeared to be sane, and on being asked how he came to pass so fearsome an object into his œsophagus stated that he did so to relieve a tickling sensation in it. Later, however, his relatives mentioned to me that he was subject to recurrent fits of insanity, and it would appear that he must have been in one of these fits at the time when he introduced the *belcha*.

I am indebted to Dr. Gouri Nath, Civil Surgeon, Hardoi, for permission to publish these notes, and to Dr. A. N. Mukerjee, in charge of the Sadr Hospital, Hardoi, for valuable suggestions with regard to their preparation.

Indian Medical Gazette.

JANUARY.

PUBLIC HEALTH IN ENGLAND.

THE annual reports of Sir George Newman are always crammed with valuable information which is communicated in forceful and attractive language. There are statistics in plenty in this report for 1926, but they are not allowed to remain as dry bones; they serve as a foundation for a living structure with active muscles, good red blood, and expressive features. Some of the more interesting statistical points are—

1. The influence of the Great War on the population. In 1911 males between 20 and 40 formed 15.58 per cent of the population. In 1921, they were only 14.1 per cent.

In Germany the corresponding figures were—15.1 per cent in 1910 and 13.7 per cent in 1919. The proportion of children under five years of age fell in England from 10.7 to 8.8, while in Germany the fall was much greater, viz., 12.0 to 6.3. From this it appears that while both England and Germany lost about 9 per cent of their males of fighting age, England lost 18 per cent of the children under 5 as a result of the war, and Germany nearly 50 per cent.

The birth rate of England continues to fall: it was 17.8 per 1,000 in 1926; the death rate was also low being 11.6 per mille. During the ten years period 1871—80 the birth rate was 35.4 per mille and the death rate 21.4, so that both have fallen approximately by one half during 50 years.

The chief causes of death were, diseases of the heart and circulation 188 per mille of deaths, pneumonia and other respiratory infection 150, malignant disease 117, diseases of the nervous system 103, tuberculosis 82, old age 54, and violence 41.

The infant mortality was only 70 per mille and the death rate for children aged one to five years was correspondingly low. It is interesting to note the decline in the mortality from the chief infectious disease between 1871—80 in 1926.

Enteric Fever ..	0.32 per mille to 0.009
Tuberculosis of the lung ..	2.13 to 0.771
Whooping cough ..	0.51 to 0.115
Measles ..	0.38 to 0.089
Scarlet fever ..	0.72 to 0.017
Diphtheria ..	0.12 to 0.077

It is rather surprising that diphtheria should show a smaller drop in mortality than any of the other fatal infections in spite of the discovery of a specific treatment for that disease. It is obvious that enteric fever and scarlet fever have ceased to exercise any important influence on the

death rate, while tuberculosis and other infections can also be classed among the "disappearing diseases." Cancer, heart diseases, and respiratory infections show no signs of yielding to the preventive measures which have hitherto been adopted, and it is clear that the next great forward movement must be concentrated on these.

Sir George Newman is far from satisfied with the existing procedure of death registration; in many cases the statistics are useless or even misleading; for example the deaths from motor accidents are not classified in such a way as to show how many drivers, passengers and pedestrians respectively are killed. In the deaths from cancer a large number of deaths are returned as being due to cancer of the liver and gall-bladder, whereas there is reason to believe that the primary seat of the disease was usually in some other organ. Many women who were known to have had cancer of the breast were shown as having died of some other disease and no reference was made to the existence of cancer which must often have been an important factor in connection with death.

In 1924 only 124 deaths were returned as due to alcoholism: it is quite clear that this figure is far from giving a true picture of the influence of alcohol on the death rate.

Sir George makes a reasoned attack on the use of the term "status lymphaticus" as a cause of death; he shows clearly that the leading text books are quite misleading in their teaching on this subject. There is no clear evidence that an association exists between the size of the thymus gland and the liability to death from trivial causes. There is a constitutional condition in which death may occur from slight causes, but the use of the name "status lymphaticus" is mischievous as it suggests that a precise knowledge exists whereas we are completely ignorant of the real nature of the condition.

The use of the medical jargon, especially in connection with endocrinology has a most pernicious effect on the mental outlook of the medical man, it lulls him into a false sense of possession of scientific knowledge; instead of seeking for the true facts he repeats a high-sounding formula. The notification of infectious diseases often fails to achieve its real object which is to give early information which will help in controlling the spread of infection. The chief obstacle in this connection is the difficulty in recognising certain diseases such as lethargic encephalitis and cerebro-spinal fever; many slight cases of these diseases must be missed. More than 10,000 cases of small-pox occurred during 1926, but there were only 15 deaths. Only half of the infants in England are being vaccinated so that there is a prospect of a steady increase in small-pox. If the disease should continue to be of an extraordinarily mild type this increase will only involve a great deal of expense and worry, but if the virulent form should make its

appearance there will be a rude awakening from the existing feeling of indifference which exists.

The British Parliament in its wisdom has decreed that exemption can be claimed from vaccination, and thus is carrying out a very interesting if somewhat risky experiment in epidemiology.

In Detroit from 1915 to 1923, there were 4,631 cases of small-pox with 17 deaths, but in 1924, there were 1,610 cases with 163 deaths including 124 cases of the hæmorrhagic type. This experience shows that virulent small-pox may appear without warning in places where the mild type had prevailed for several years.

Scarlet fever continues to be of an extremely mild type: two outbreaks were traced to the contamination of a milk supply by an unsuspected carrier of infection. The use of the Schick test and of protective inoculation against diphtheria is gradually extending in England but the country as a whole cannot be said to have attained to a satisfactory degree of control of this disease. The fall in the mortality from 10.3 per cent in 1911 to 5.9 per cent in 1926 may be due in part to the diagnosis of mild case on bacteriological grounds: it is suspected that some of the "positive" cases are mere carriers of the bacillus who are suffering from some other throat infection, whereas formerly only clinical positives were included as diphtheria.

Influenza became exceptionally prevalent early in 1927. Protective inoculation was of doubtful value in preventing attacks, but the inoculated suffered much less from pneumonia and bronchitis than the unprotected; deaths were chiefly in the very young and very old, in striking contrast to the great pandemic of 1918 and 1919, in which young adults suffered severely. Nothing important was discovered with regard to the bacteriology of influenza except that in a carefully controlled small group of people there was a sharp rise in the frequency of healthy pneumococcus carriers just before the disease appeared: there was also an increase in the percentage of carriers of the Pfeiffer bacillus, but this was not so sharp and it occurred rather later than the rise in the pneumococcus carriers.

Encephalitis lethargica comes in for special notice; the number of cases notified in 1926 was less than half that of 1924, but it would be premature to assume that the disease will continue to decline. Many cases are mild and atypical so that diagnosis is often impossible. There is a very valuable report of a study of the disease by Dr. MacNalty and Dr. Ashton in which the various types of the disease are described. The initial symptoms are often those of headache and pyrexia, sometimes with slight catarrh, so that influenza is frequently diagnosed. Drowsiness may be the first symptom, diplopia at the onset was common and was an important diagnostic feature; hiccup, speech changes and severe conjunctivitis were important initial symptoms. There was drowsiness

during the illness in two-thirds of the cases. Carriers, acute cases and unsuspected cases are regarded as possible sources of infection. Chronic carriers are believed to occur, though exceptionally. Acute poliomyelitis was very prevalent in 1926. An excellent account of the chief features of the disease is given in the report and it is interesting to find that the first account of the disease was written by Dr. Michael Underwood, an English physician, in 1784. The disease became epidemic in England in July 1926 and continued to be prevalent till February 1927. It was most common in some of the South Eastern countries and in the Midlands; there were few cases in London. Though it was often difficult to detect the direct path of infection from person to person it appeared probable that such communication was the rule, either by convalescent cases, healthy carriers or actual cases, including mild unrecognised forms of the disease. Adults were sometimes attacked, though the vast majority of the cases were in children under 15 years of age. The path of entry of infection is believed to be by the upper respiratory tract, presumably by droplet infection. The disease at the onset is an acute febrile infection, often with catarrhal manifestations suggesting influenza; next come pains in the back and limbs, drowsiness or even stupor, and stiffness of the neck muscles. At this stage the cerebrospinal fluid becomes altered: it escapes under pressure and shows a high white cell count, first polymorphonuclear then small mononuclear. Next come the various paralytic phenomena which may be due to affection of regions of the spinal cord, bulb, cerebral cortex, cerebellum, or peripheral nerves. The commonest form is the well known spinal form with paralysis of certain groups of muscles.

The account of the disease contained in the report ought to be read by all who wish to know the variations of this very protean and puzzling malady. Isolation of all patients, including those who are merely under suspicion, appears to be the best means of dealing with the disease. Cancer is slowly increasing in prevalence, but not to such an extent as to prove that the disease is really becoming a greater menace than formerly. Better diagnosis and the increasing longevity of the people of England amply account for the increase in the total number of cases.

It is quite obvious on the other hand that there has been no appreciable practical result from the great efforts which are being made to solve the cancer problem. The Cancer Committee of which Sir George Newman is chairman is exploring every likely avenue of attack on the stronghold of cancer; very valuable work has been done, but the writer of this review has always been of opinion that the most promising line of work is to argue from the known to the partly known, and if this process should yield good results to go on to argue from the newly

JAN., 1928.]

solved to the still unsolved parts of the problem. We do know how to prevent the *kangri*-burn cancer of Kashmir, radiographer's cancer and various other forms of the disease in which a known irritant is an essential factor. There are other forms of the disease in which a partly understood form of irritation is likely to be a factor of great importance. If these forms, such as cancer of the penis and stomach can be controlled by the removal of the most probable sources of irritation, there will be good grounds for applying the same principles to the remaining forms of cancer, especially as most of them are known to occur at sites where irritation is very likely to occur.

We make no apology for returning again to this subject: its importance is sufficient to justify the most persistent advocacy of a procedure which appears to us to hold out the promise of a considerable measure of success.

Tuberculosis.—This is a disappearing disease in England. In spite of the increase which took place in tuberculosis of the lung during the war the deaths have fallen from 38,422 in 1911 to 30,108 in 1926; the deaths from other forms of tuberculosis have fallen from 14,698 to 7,417.

The decline in the disease is probably due to an increase in the resisting powers of the population rather than to the special measures of control which have been adopted. In 1918 the deaths from tuberculosis of the lung increased to 45,338 from 36,203 in 1913 so that food supply appears to play a very important part. The various local tuberculosis schemes have been shown to produce excellent results and when these are extended all over the country they will doubtless do much to hasten the diminution of the disease.

Village settlements and occupation colonies have been shown to form a solution of the difficult problem of dealing with the patients who have improved by sanatorium and hospital treatment. Sanocrysin treatment has been tested and found to be of value only in certain selected cases. The Spahlinger treatment is regarded as being worthy of further trial under scientific control, but unfortunately Dr. Spahlinger has refused to supply the necessary materials for the requisite tests.

Calmette's immunization method is being investigated under conditions approved of by Calmette himself, it is regarded as being *sub judice* as yet.

Organised treatment centres for venereal disease are doing excellent work; not only do they yield important results in themselves, they also serve to raise the standards of treatment by private practitioners, who will otherwise find themselves at a disadvantage if their treatment is found to be inefficient when compared with that which is available at the centres.

Syphilis may well be found to be capable of control within the next few years, gonorrhoea will

follow, but more slowly as there is no really specific treatment for this disease.

Maternal mortality remains almost stationary, but the measures which are being adopted by the Ministry of Health are bound to produce an improvement when they are more widely and strictly enforced.

Maternity and child welfare institutions are increasing in numbers and efficiency, and the important problem of the "pre-school child" is being tackled with energy.

The Insurance Medical Service has passed through its difficult and critical early stage; no less than 13,649,597 insured persons are attended by practitioners on the lists of the Ministry and a sum of £8,621,638 is spent on medical benefits. Disciplinary action is taken in all cases in which complaints are received against insurance practitioners: grants are withheld in cases of proved default, but the number of cases of a serious nature is surprisingly small. Various minor problems still arise in connection with the insurance scheme, such as the question of economy in prescribing.

Health education is actively promoted by a number of the Insurance Committees, but the absence of a specific allotment of funds for propaganda work had been an adverse factor; some committees have found the necessary funds, others prefer to devote all their income to medical relief.

The chapter on nutrition is a most valuable contribution to an important subject; it is singularly free from faddism and deals in a sane and rational manner with the food problem.

Milk is shown to be a most valuable food in early life, and the average daily consumption of half a pint daily is regarded as quite inadequate. Milk control is one of the most important functions of the Ministry of Health; it is becoming more and more effective from year to year.

Adulteration of milk and other foodstuffs has declined in a remarkable manner since 1880.

Food poisoning has always been a subject of concern to the Ministry though the actual deaths from this cause are relatively few. Several outbreaks have been found to be due to infection by dysentery bacilli of the Flexner or Sonne groups.

In one outbreak typical canned meat poisoning occurred simultaneously with paratyphoid B. infection: the person who handled the toxic canned beef was a paratyphoid carrier; she ate some of the beef and had diarrhoea; apparently she then infected the toxic beef with paratyphoid organisms in the course of handling it: some of her customers had food poisoning, others had paratyphoid fever. The Aertycke bacillus was responsible for outbreaks of ham, bacon, brawn and egg-poisoning.

Artificial light treatment is discussed and the opinion is expressed that the carbon arc light is the most valuable source of light. The mercury vapour tungsten arc lamps have a rapid and active action, but they are believed to be of low

penetrative power and they have the disadvantage of falling off rapidly in power after prolonged use. The necessity for skilled control in the employment of artificial light treatment is emphasized: positive harm has resulted not infrequently from its use.

Under conditions of strict control ultra-violet light does not yield the striking results which have been claimed for it by some enthusiasts.

Deaths from anæsthetics were 556 in 1926, as compared with 276 in 1911, but the great increase in the number of surgical operations fully accounts for the larger numbers. An added difficulty is that it is not easy to separate the genuine anæsthesia fatalities from those due to operative shock and other conditions.

The Ministry of Health carried out a large number of investigations of disease, including several international enquiries.

The spirit which imbues Sir George Newman is well expressed in the following words:—

"The progress of a nation's health is a secular movement.*.*.* As it must inevitably be the primary so it is perhaps also the most absorbing, alluring and irresistible of all the active forms of human effort. For here we are dealing with the proposition of remaining alive in the world, of enlarging the content of life, of increasing its capacity, of making it longer, happier and more constructive for all men. Can any enterprise be greater? We, who are the medical or administrative servants of this undertaking, must not allow ourselves to become customary or routine in thought, action or outlook. The efficient medical officer of a Local Authority needs, of course, professional competence and good judgment, but he should also have a thirst for knowledge, foresight, a sound historical sense and high purpose. Without these characteristics he is scarcely earning his public pay."

The paragraphs of the report which deal with the function of the State in stemming disease constitute a weighty pronouncement which ought to be read and meditated on by every one who is interested in the welfare of the people of India. It shows what has been done in England by State intervention to combat disease and death. The methods which have had such a measure of success in that country may not be suitable for employment in India but the great underlying principles are the same for all countries. For this reason we have taken the liberty to quote paragraphs 342 to 345 of Sir George Newman's report for 1926, verbatim below.

In expressing a general opinion on this report "On the State of Public Health," it is difficult to avoid the use of language which would suggest exaggeration or fulsome praise.

If the existence of such a suspicion should induce our readers to read the report and judge for themselves we feel that two happy results will be achieved, the reader will derive immense benefit and we shall be absolved from the charge of

unreasoning enthusiasm. Those who read the report must congratulate Sir George Newman on his good fortune in having found so congenial an occupation, and England on having found the ideal medical administrator.

J. W. D. M.

A SNAKE-BITE POSTER.

THERE has long been needed a really authoritative and reliable snake-bite poster for use in hospitals, dispensaries, and public institutions in India. At the suggestion of Messrs. Thacker, Spink and Co., a large coloured snake-bite poster, $3\frac{1}{2}$ by $2\frac{1}{2}$ feet in size, has now been prepared at the Calcutta School of Tropical Medicine; to be issued as a supplement on payment to subscribers to the *Indian Medical Gazette*. It is illustrated with 14 illustrations, mostly in colour; and every attempt has been made to reproduce the exact natural colouring of the species concerned.

The letterpress of the poster deals, first with the distinction between colubines and vipers; secondly, with the points of identification of the really important poisonous snakes of India, viz., the cobra, king cobra, banded krait, common krait, the coral snakes, Russell's viper, the *Echis carinatus* or *phoorsa*, and the pit vipers. This part is very fully illustrated, the illustrations being taken from Fayrer's famous *Thanatophidia of India*, Colonel Wall's publications, and Colonel Acton's article on poisonous snakes in Byam and Archibald's *Practice of Medicine in the Tropics*; as well as from mounted specimens of the snakes concerned. The third section gives instructions for the treatment of snake-bite, and is mainly based on the work of Acton and Knowles on the subject in the *Indian Journal of Medical Research* for 1914-15.

The poster will be supplied to subscribers to the *Indian Medical Gazette*—(one copy only to each subscriber)—on application to Messrs. Thacker, Spink and Co., P. O. Box No. 54, Calcutta, at the following terms:—

Unmounted, on paper, (including packing and postage), Rs. 2.

Mounted on linen, and with rollers, ready to hang on the wall, (including packing and postage), Rs. 7-8. Copies are now available.

WHAT THE STATE IS DOING TO STEM DISEASE.

An Extract from the Report by Sir George Newman on the state of Public Health of England for 1926.

"342. The problem then is to prolong man's days by reducing premature mortality, to remove the causes of disease and physical disharmony and their results and to enhance the physical and mental capacity of all classes of the nation. It is a large proposition. A moment's consideration will show that many different factors and agencies, social as well as medical, will play an essential part in this vast enterprise. There is hardly a central department of the State

which will not, consciously or unconsciously, make a contribution to the condition of the public health; there is no branch of the service of the Local Authority which will not, directly or indirectly, play its share. The social, political and economic life of the people, their wages and labour, their habits, customs and circumstances, their educational equipment, will all conduce, or be antagonistic, to their physical welfare. The issue is something infinitely wider than the science and art of Medicine, yet that science and art is the focal point.

343. There are, however, three great spheres of Public Medicine which fall within the province of the State. First, there is the medical profession; secondly, there is a sanitary environment and sanitary institutions; and thirdly, there are the public medical services. In a general way it may be said that the Ministry of Health is concerned with all these matters. In this country medical education is provided under the Universities upon the advice of the General Medical Council under the Medical Acts, and within the last half-century the State has imposed upon the profession an ever-increasing series of statutory duties which form in some ways the foundation of the State's defences against disease. More than that, the State has invited the medical practitioner into the service of the community, providing appropriate safeguards for the protection of his individual privileges and rights as a member of a learned profession having a particularly intimate relation to the sick person. This formal association of the doctor with the State began under Act of Parliament nearly a century ago in the establishment of the poor law medical service, which in due time gave birth to the public health service, which in its turn comprised public medical services for the mother and her infant and for the school child. In more recent years there was organised by the State the health insurance service and national medical research. In other words, the State has designed machinery providing facilities by which the medical man, if he so wishes, may serve the State in various capacities—in the medical service of the sick poor, the mother, the infant, the school child, the factory worker, the insured person, the mentally deranged, the physically defective, as well as in what is known as "the public health service." Even medical education and medical research are now subsidised by the State. It is obvious that there is no central department more concerned in these developments than the Ministry of Health, because it is impossible for Parliament to devise adequate health arrangements for a nation without a well-equipped and sufficient medical profession. In the evolution of State Medicine we have come to a stage of partnership between the State and the medical profession, and between all branches of that profession, in the behalf of the people as a whole.

344. Long before our own times the State had called upon Local Authorities, particularly the City of London, to concern themselves with the sanitation of the area for the governance of which they were elected to be responsible. It is now common knowledge that Local Authorities have had imposed upon them by Parliament a large number of statutory duties in respect of sanitation, nuisances, water-supply, food control, river pollution, housing, infectious disease, hospital accommodation, and so forth. These matters form the solid foundation of all enduring public health work. It must never be forgotten that a *sanitary environment is the essential basis of all effective medical services*. For the purpose of such services is to make medical facilities available to the individual, yet they can as a rule be neither available or effective in insanitary circumstances. Now what is the form of existing health services and what is their answer to the problems of disease with which we are faced? I think it may be set out concisely as follows:—

(a) First, there is *ascertainment* of the situation—notification of births, the certification of sickness, the notification of infectious disease, the registration of deaths, the account-keeping of the physical condition and progress of the English people. The public is deeply concerned in this verification and should do all they can to assist. Records must not be overdone, but they must after all be adequate and correct. It is as futile to complain of the collection of vital statistics as it would be for a business man to complain of accounts of income and expenditure or of profit and loss.

(b) Secondly, *there is maternity and infant welfare*. A nation that fails to safeguard maternity and conserve its infant life would be adjudged to be neglectful of its source, a very wasteful and far-reaching degree of neglect.

(c) The *School Medical Service* is another means of finding out whether anything is physically or mentally wrong with the rising generation and providing a timely remedy. With maternity and the care of the infant it lies at the foundation of all solid building and good construction work. Both movements have abundantly justified themselves, though neither lacks helpful critics.

(d) A fourth means invented by the State and the people thinking together—and as a living statesman said "the people is the State and the State is the people"—is the *National Health Insurance Act*. The State, in fact, is the people organised for governance and by the terms of this Act the majority of the workers have been insured against sickness, and have now available a medical service of growing importance and utility. The history of its development will be referred to below.

(e) Older than any of these is the *Poor Law Medical Service*, which sprang out of the reorganisation of the Elizabethan Poor Law in 1834 and which deals with the substantial group of the population who are necessitous and cannot even find the wherewithal for sharing in an insurance system.

(f) At the time of the beginning of the Industrial Revolution at the end of the eighteenth century, there arose a voluntary movement, originated by public-spirited medical men, which sought to protect the factory worker from the risks of his employment. As has happened all through our history, the State in due course adopted the ideas of the more enlightened employers, and devised what we know as the *Factory Acts*, which, though administered under the Home Office, are first cousins of the Public Health Acts, the administration of which is supervised by the Ministry of Health, and they must take their place in this category.

(g) Lastly, in recent years Parliament has found it necessary to establish a series of special means for a direct attack upon some of the more insidious and incapacitating maladies, such as small-pox and other infectious diseases, lunacy and mental deficiency, tuberculosis, venereal disease, ophthalmia of the newborn, blindness, and dental decay. We have indeed also the beginnings of a direct attack upon cancer, rheumatism, and the epidemic nervous disorders.

These seven "public medical services" illustrate the form in which the science and art of Preventive Medicine has been expressing itself during the last generation. They are the superstructure standing upon the foundations of sanitation, food control and improved environment. What has been their answer? I avow my belief that they have changed the face of England. Even more than that, with all their limitations and imperfections, they have, though so often criticised at home, been copied all over the world. We are a nation which flourishes on criticism; it is our incentive to improvement. The improvement and perfection of these three implements of Public Medicine—a competent medical profession, a sanitary environment, and economic and effective public medical services—is, as I have said, a matter of time and

vigilance, of steady growth and wise amendment. In them we are building for generations to come. But of their early results we have evidence which cannot be gainsaid.

345. The evidence is so manifold and varied, it is so personal and local, so largely economic and social, that a volume would be necessary to present it. But a key is at hand in the story of mortality as set out in the annual returns of the Registrar General. We must take a long measuring rod and go back 80 years; we must avoid the fallacies which arise by comprising one year too closely with another; and bearing these two points in mind, we may study, and reflect upon, these extracts from the ledger of a nation. The declaration is so simple and obvious that he who runs may read.

England and Wales—Annual Standardised Death Rates.

Death Rates at Five groups of Ages, and Infant Mortality at certain periods.

Period.	DEATHS OF PERSONS PER 1,000 LIVING AT SUB-JOINED AGES.						Deaths of Infants under one year of age per 1,000 births.
	All Ages (Standardised.)*	0	5	15	25	65 and upwards.	
1845—50 ..	22·4	68·7	7·6	8·7	15·9	97·1	15·7
1866—70 ..	21·2	68·1	6·0	7·1	15·4	91·3	15·7
1886—90 ..	18·5	56·9	3·9	4·7	13·8	91·5	14·5
1906—10 ..	14·4	41·7	2·7	3·2	10·7	81·9	11·7
1921—25 ..	10·9	24·7	2·1	2·9	8·8	76·0	7·6

* The death rates in this column are standardised to the sex and age constitution of the population enumerated in 1901.

These figures mean that in spite of an enormous increase of population without increase of home territory, the total death rate and the infant mortality rate of the nation have been halved inside four generations; that the mortality of childhood is one-third of what it was eighty years ago; and that the 'expectation' of life for a child born in this country to-day is not less than seventeen years longer than it was for a child born in 1846. This is the answer."

THE INDIAN SCIENCE CONGRESS, 1928.

We have been asked to announce that the Medical and Veterinary Section of the Indian Science Congress, 1928, will *not* be held. Owing to the fact that the biennial Congress of the Far Eastern Association of Tropical Medicine was held in Calcutta from December 5th to 10th, 1927, it was doubtful from the first whether there would be a sufficient number of members attending, or a sufficient number of papers presented for the Medical and Veterinary Section of the Indian Science Congress—to be held in Calcutta in January 1928—to warrant the holding of this section. Some 300 circular letters were sent out to those members of the medical and veterinary professions in India who usually attend or submit papers to the Indian Science Congress, and the replies were almost unanimously in the negative. Only eleven persons expressed their intention of being present, and only four members proposed to read papers.

Under these circumstances, the Executive Committee—wisely, in our opinion,—has decided

that it is impossible to hold the Medical and Veterinary Section of the Congress in 1928, and it has been abandoned. This, however, will not affect the general meeting of the Congress, which will be held as usual.

The annual Indian Science Congress in 1929, will be held in Madras. By January 1929, a sufficient interval of time will have elapsed after the Congress of the Far Eastern Association of Tropical Medicine to allow of the accumulation of papers of sufficient merit; and it is hoped that the meeting of the Medical and Veterinary Section of the 1929 Scientific Congress may be a

really representative and valuable one and a success. Those who intend to read papers or to be present at the 1929 Congress are invited to communicate with Lt.-Col. R. Knowles, I.M.S., Calcutta School of Tropical Medicine.

Current Topics.

Looking Backwards.

We have recently received, through the courtesy of Major J. C. John, I.M.S., Superintendent, Orissa Medical School, Cuttack, a most remarkable document. It is a *verbatim* copy of official instructions published in the year 1817 by the Medical Department (presumably of the East India Co.) of how to treat cases of cholera. It is one of much historical interest and value. The official instructions for the treatment of cholera in 1817 were as follows. Apparently 12 grains of calomel within two hours was a standard remedy.

Memorandum. Cholera Morbus.

The most alarming symptom in this disease is the sudden prostration of strength at the very commencement. The patient, while walking or engaged in his usual occupation without any previous warning symptom, falls down and is immediately seized with vomiting, at the same time that cold clammy sweat breaks out over his body. His pulse can scarcely be felt, and his debility is such that he is unable to move from the spot without support. In some cases the patient has died within half an hour of the first attack. But in general, where no remedies are used, it proves fatal in ten or twelve hours. During the latter part of this period especially, the patient, when sufficiently sensible to describe his own

sensations, complaints of a painful sense of weight and heat in his stomach and bowels, and his excretions prove sufficiently the vitiated nature of their contents. When the irritable state of the bowels has been checked in the first instance, and the debility in some degree removed, a relapse is frequently produced by loading the stomach with food, and this is generally very speedily fatal.

The indications of cure therefore seem to be:—

1st.—To support the patient's strength;

2nd.—To remove the irritability of the stomach and bowels, and thus prepare the way for medicines which are given;

3rd.—To expel their morbid secretion, and

4th.—To restore the healthy action of the stomach before calling its digestive powers into action.

To answer the first of these purposes, we have an excellent and ready resource in any of the common spirituous liquors, and in urgent cases spirits of hartshorn or ether may be had recourse to. The dose of these remedies must be regulated entirely by the state of the patient. In common cases a medicine glass full of brandy with an equal quantity of water will restore the patient so as to remove all immediate danger of sinking. In other cases the same quantity of brandy must be given undiluted, or one drachm of ether or two of spirits of hartshorn, in one ounce of water. The exhibition of these or similar stimulants not only restores a degree of animation to the patient, but procures for him some respite from vomiting. This will, however, except in very slight cases, soon recur unless opiates be given to prevent it. Fifteen drops of laudanum may be given in two tea-spoonfuls of water, and if this should have the effect of keeping off the vomiting for some minutes the same quantity may be repeated when it recurs. Should the vomiting come on immediately after taking the first dose, the second should be increased to 20 or 25 drops, and in similar circumstances, the third dose to 30 or 40 drops, and so on after each attack of vomiting.

Opium may likewise be applied externally to the stomach, moistened with water or spirits, from 5 to 10 grains, mixed with water and rubbed with the palm of the hand over the upper part of the belly is often sufficient to stop the vomiting. In many cases it will be desirable to combine the opiate with the stimulant and in slight cases the opiate is alone required.

By these means the irritability of the stomach will be speedily subdued, and it will be brought to a fit state to retain the purgative medicines that are to be given with a view to expelling the morbid secretions of the intestine, calomel readily suggests itself as an appropriate remedy where the action of the liver is more particularly disordered. Care must be taken, however, not to give a large dose at once, which would infallibly bring back the vomiting. One pill of 3 grains may be given at first, and at intervals of half an hour or forty minutes each, two more. Should these not produce the desired effect in five or six hours, recourse must be had to a solution of an ounce of Epsom salts in ten or twelve ounces of senna infusion. Of this a Madeira glassful may be given every ten minutes while necessary. Compound aloetic pill may be combined with the calomel with great advantage; the quantities of each in one pill being two grains of calomel to three of aloetic pill. During the exhibition and operation of these purgatives the patient's strength should be constantly attended to, and when necessary supported by small quantities of hot brandy and water, given from time to time. An ounce of infusion of cherata taken twice a day, for three or four days, after the first attack will restore the stomach to its natural tone, or small doses of rhubarb of 5 or 6 grains each may be given evening and morning.

Cohimbo root in powder is also an excellent medicine in this stage of the disease. For some days after an attack of this disease the patient should avoid exposure to heat and should abstain from all heating and greasy food, and confine his regimen to the plainest and most simple diet. Further it will be proper to guard against a rule of practice which is not applicable to the form in which cholera morbus is at present most commonly

seen. The rule alluded to is that of administering diluents such as warm water, weak gruel in order to wash out the contents of the stomach before any medicine is given. When the progress of the disease to its termination in death is so rapid, as in many instances that have recently appeared, nothing can be more dangerous than any delay in supporting the patient's strength, and still more is that delay to be deprecated when the time is lost in the use of means that in the first instance increase the violence of the disease.

Medical Department,
The 13th September 1817.

Malaria and Tuberculosis.

By M. FREIMAN.

(*Journ. Trop. Med. and Hyg.*, July 1927, p. 181.)

FREIMAN gives his experiences in Cyprus and shows that in patients clinically free from signs of tuberculosis, the onset of malaria precipitates an acute tuberculous development, while recognisable consumptives with malarial infection have exacerbations, sometimes with a fatal termination. To explain the mutual influence of malaria on tuberculosis he made an examination of 406 cases of acute and chronic malaria by the Von Pirquet reaction. He concludes that: (1) malaria transforms the positive cuti-reaction to negative; (2) the anergy (i.e., negative cuti-reaction) in malaria is due to the malarial intoxication; (3) if malaria is treated, the anergy can persist from 20 to 200 days; (4) creating anergy, malaria deprives the organism of its tuberculous anti-bodies and exposes it to the outer and inner tuberculous infection.

Diathesis, or the Influence of Soil in the Causation and Treatment of Disease.

(*Glasgow Med. Journ.*, August, 1927.)

In a recent issue of the *Glasgow Medical Journal*, Ramsay makes some interesting observations on "diathesis"—the inherited tendency or proclivity to any particular disease. "The diagnosis," he says, "is often written on the countenance of the patient, if only the doctor had cultivated the kind of experience whereby he might have been able to recognise it"; and he openly deprecates the extent to which this important factor has been neglected nowadays as a result of the dominance of the laboratory in the realm of medicine. The "scientific methods" of the laboratories are tending to displace the art and science of medicine.

Ramsay considers in detail three distinct types of diathesis:—(1) the neurotic, (2) the arthritic, (3) the scrofulous.

1. *The neurotic diathesis.*—The neurotic patient is well known, and it is important to remember that his peculiar tendencies develop during the first five years of life. Of spare build, restless and unwearying, with a mind so active that it allows neither himself nor his immediate circle any repose; he feels pain very acutely, and, consequently, what may in reality be a very trifling ailment assumes to him very serious proportions when interpreted and exaggerated by his nervous disposition. His nerves, over-developed, tyrannise over his body, and his excellent memory makes him a terror to a youthful doctor, who is never allowed to forget anything he may have said to him. Full of fads, he has often real idiosyncrasies in regard to drugs, and is therefore a most difficult patient to treat, for every prescription, no matter how carefully considered by the doctor, is said to disagree, and will in all probability have to be discontinued. On each succeeding visit the patient will say he feels no better, and straightway without any evidence of emotion will repeat a tale of endless suffering. He is always on the outlook for an opportunity to prove the doctor wrong and himself right, and although he may be most punctilious in taking the medicines prescribed, has little belief in their power to do him any good.

2. *The arthritic diathesis.*—This diathesis is a well-marked and widely-spread type, and includes persons popularly called "gouty" or "rheumatic." It exists among all ranks of society, and is found at all ages, being more frequent among children than is generally supposed. Much useful information regarding it will be obtained by careful routine examination of the urine, which generally contains uric acid in excessive amount. The "cayenne pepper" deposit is in many instances noticed by the patients themselves, and in the case of children the mothers invariably draw attention to it. The other secretions of the body are hyperacid and very irritating. The acid perspiration renders the epithelium vulnerable, and consequently cutaneous eruptions are of frequent occurrence. The patients themselves are big and stout, with a florid complexion and a genial exuberant manner. As a rule, they are hearty eaters, and in their younger days their digestion was quite able to cope with the many demands made upon it. They are in the habit of boasting that they never require a doctor and never take medicine. As the years pass, however, they are not so sure about their health; they tend to suffer from acid dyspepsia or to be annoyed by eruptions on the skin—the one condition often alternating with the other. They find too as they get older that they must change their habits with regard both to food and to stimulants. They must eat less, be very careful in the use of alcohol, and substitute regular exercise for desultory attempts at exertion; otherwise they may be suddenly cut off by an attack of pneumonia or other acute disease, or they may be invalidated by a constant series of chronic degenerative ailments, which are likely to terminate fatally from renal cirrhosis or from cerebral hæmorrhage. That description corresponds in brief to what Laycock has called the sthenic or sanguine form of the arthritic diathesis; but an asthenic or melancholic modification is frequently seen. These patients have a great tendency to obesity, with poor muscular development, and are usually slow in their movements, and generally of a sluggish disposition. Their outlook on life is pessimistic, probably due to the fact that their power of digestion is quite unequal to the quantity and quality of the food they habitually consume.

3. *The scrofulous diathesis.*—The scrofulous diathesis is very common, and is for the most part met with in children under ten years of age. Some of those affected present the outward appearance of good health, but the majority, owing to defective assimilation, are either abnormally pale or unnaturally livid. They have too obviously inherited the miserable legacy of constitutional weakness, and the inherent vulnerability of their tissues has been intensified by improper dieting and by overcrowding in insanitary houses.

There are two distinct types of the scrofulous diathesis.

1. *The ugly type.*—It is easy to recognise these slow lethargic children by their pale skin, coarse features, snout-like mouth, and short neck, thickened by masses of enlarged suppurating glands.

2. *The attractive type.*—Is in marked contrast to the former. The children are quick and alert, both physically and mentally. As a rule they have regular features, with a delicate pink and white complexion, long silky eyelashes, and although the glands in the neck are usually enlarged they do not form the large suppurating masses so characteristic of the ugly form of scrofula.

In both types, but more particularly in type one, after the disease has existed for several weeks, the eyelids, nose, and upper lip become swollen, and an eczematous eruption appears on the face. The acid secretions excoriate the skin and frequently cause a fissure at the outer canthus. This causes great pain and bleeds freely whenever the lids are forcibly separated. It is by no means unusual for the conjunctivitis to alternate with suppurating of the middle ear, and with eczema of the hairy scalp or other parts of the body. In every case nutrition is seriously impaired, and the coated tongue studded with large red papillæ is evidence of the irritable condition of the mucous membrane of the whole intestinal tract. Sometimes there is constant craving for food, and invariably more is eaten than can be digested; fermentation results, the belly becomes distended, and

the alvine evacuations have an offensive smell and an abnormal appearance. The urine is scanty, high coloured, deposits urates, and often contains indican and traces of sugar. The skin is pale and rough, the flesh hangs loose, the hands and feet are usually cold, the head perspires freely, and the hair is infested with pediculi. If, after a time, the system becomes infected by tubercle bacilli the joints, both large and small, are frequently destroyed by tuberculous inflammation of their synovial membranes accompanied by caries and necrosis of the bones. Severe ectropion—causing hideous disfigurement—will arise if bone necrosis occur in the neighbourhood of the orbit, and indelible scars invariably result if there has been suppuration of lymphatic glands in the neck or elsewhere. The clinical picture is one of bovine tuberculosis, and in all probability infection has reached the patient through the alimentary tract.

(We would advise our readers to assimilate these remarks in conjunction with the article on "The Constitutional Factor in Disease," copious abstracts from which appeared in Current Topics in the August 1927, number of this journal.—Ed., I. M. G.)

The Scientific Study of Death.

We have received from Dr. Arthur MacDonald, The Congressional Apartments, 100E, Capitol Street, Washington, D.C., U. S. A., a scheme of very considerable interest, details of which we publish below. Dr. MacDonald claims—we believe rightly—that living mankind has not made a sufficient study of the dying state; and he considers that such a study would lead to the far more humane treatment of the condition of the dying. (As far as we know, this subject has been the subject of special study by only one author—William James, in his *Study of the Emotions*. As far as we can recollect from his book, he claims that the vast majority of dying persons are completely unconscious that the world has already passed them by; that their end is "as a dream.") But such speculations are subject to far more exact investigation than has previously been given to the subject, and Dr. MacDonald claims that this matter should be investigated.

The author himself is in many ways a remarkable man. Educated in America, Germany, and France, and at the chief medical schools in each of these countries, he is a member of Congress, and has tried to stimulate international interest in anthropological observations. Recently, at the age of 70, he had himself overhauled from A to Z by ten members of the staff of the Johns Hopkins University. Every physical system was tested, including fractional test meals, barium-x-ray studies of his intestinal tract, urine analysis, electric cariological studies, etc. He claims that the complete analysis so presented gives the complete picture of a more or less normal professional man of 70 years of age; and proposes, after his death, to present his body to the same University for *post-mortem* study in order to verify or refute the findings during old age. We regret very much that the complete analysis of the findings which he has sent us are too detailed for publication, as our space is very limited, but, at least, the idea is an excellent one.

A Systematic and Scientific Study of Death in Man.

By DR. ARTHUR MACDONALD,
Washington, D. C.

In order to encourage a systematic and scientific study of the dying time, I would suggest that Medical, Anthropological and Psychological Societies pass some such resolution as—

Resolved: That the———Society of the———, favours the scientific and systematic study of the physiology and psychology of death in man, and requests its members to make such studies in every case of death, when there is opportunity.

It is a curious fact that as yet there seems to have been no systematic and scientific study of human death. There have been more or less sporadic efforts to make such investigations in exceptional and interesting

pathological cases. But the regular order, so to speak, or the average manner of death is not known. Some of the main reasons for such study are:—

(1) To gain trustworthy and general knowledge of what most often takes place in the dying hour, including details.

(2) To learn the manner of death for different diseases and the percentage of those conscious and unconscious.

(3) To find in what percentage of cases there is severe pain, slight pain, and no pain, and nature of the pain.

(4) To note details in exceptional and special cases and the causes of these phenomena, and the length of dying time, and nature of pain, if any.

(5) To determine the characteristics and differences in dying between infants, children, adolescents, adults before middle life, during middle life, in old age, and from 80 to 100 years of age; including points under numbers 2, 3 and 4 for their ages.

(6) To present eventually a general picture of the dying time, based upon a sufficient number of observations, and with instruments of precision when possible.

(7) That, with such knowledge, the treatment of patients during the dying time may be more humane and delicately carried out.

(8) That in cases that are liable to be painful, proper precautions may be taken in advance, so that pain may be avoided or greatly lessened.

(9) That, finally, the knowledge of the dying time may be so increased, that physical death will cease to be feared or dreaded by all persons, since through such knowledge pain may be practically eliminated, and death may be made easy, gentle, and placid.

The British Social Hygiene Council.

GREAT progress in the means of combating venereal disease throughout the British Empire has been made during the past year, according to the official account of the meeting of the British Social Hygiene Council held in July 1927 at Carteret House, Carteret Street, London, S. W. 1.

A special effort was made as regards India, where it was found that in the various Provinces visited congenital syphilis was prevalent, and that the social conditions were such that venereal diseases were disseminated among adolescents as well as among adults.

Many recommendations were made, including the provision of increased hospital accommodation, of ante-natal beds and of post-natal care, while it was also urged that there should be improved training of medical men and improved treatment of venereal disease, and of a free bacteriological service.

From the purely educational standpoint emphasis was laid on the importance of biological teaching, while from the social standpoint it was recommended that full information should be given; that once public opinion had been aroused the commercial interests in prostitution should be penalised, and that cinema films unsuitable to India should be banned. The Central Government has been invited to provide—

(a) for the diagnosis and treatment of venereal disease, and for recreational facilities for the Mercantile Marine;

(b) to co-operate with the Provincial Governments in securing the services of a biologist and psychologist during the winter season of 1927-1928 to initiate the additional teaching of biology and social hygiene, and

(c) that with the help of the Government of India the British Social Hygiene Council through an India Advisory Committee should make themselves responsible for the Indianisation of the dramatic films for propaganda purposes.

In each of the Provinces visited, Bombay, Bengal, Burma, Madras; in the Indian States of Mysore and Baroda, and also the Island of Cyprus, Social Hygiene Councils affiliated to the British Social Hygiene Council have been established.

Similar progress was reported from other parts of the Empire, though the Council has to deplore that in Ceylon there is a local agitation to remove the salutary embargo that exists on unauthorised persons visiting ships in port.

During the past year many conferences have been held and others are in progress. Among the points raised are the necessity of technical education of medical men by experts, the combination for the purchase of drugs, the establishment of scholarships for the proper training of medical men, and the provision of decent shore sleeping accommodation and recreational facilities in colonial ports for the Mercantile Marine.

The Mercantile Marine has very greatly occupied the attention of the Council for the past year, and generally speaking the main objectives have been to provide proper facilities for treatment, and adequate recreation of all sorts. The representatives of many towns and organisations of many towns have been involved, and a number of committees established.

The whole issue of broadcasting has been raised, and while the general position is under consideration, talks on biology, and physiology have been given, respectively, by Professor Julian Huxley and Professor Winifred Cullis.

A Summer School in connection with the activities of the Council was held for the first time at Balliol College, Oxford, and a second Summer School was also held from August 3rd—9th, at Keble College, Oxford.

A new edition of the *Speakers' Handbook* is in course of preparation, and during the last spring a conference was held on the whole problem of solicitation. The problem of mental deficiency was also considered, and it is hoped the new amending bill will soon become law.

The Council has supported the proposal made by the Commonwealth Fund of America as to the establishment of a Child Guidance Clinic in England. It has also urged that the Medical Research Council should promote investigations that may lead to the discovery of an effective cure for gonorrhœa; the Research Council are naturally also deeply interested in the problem, and correspondence is proceeding between the Medical Advisory Board of the Council and the Medical Research Council.

Other matters that have occupied the attention of the Council have been congenital syphilis, the after-care of women and children suffering from venereal disease, and the development of the Medical Department, which has proved its usefulness by the large number of enquiries received, to which replies have been given, enquiries coming from all parts of the world.

The propaganda work of the Council has been as active as ever; the Council has participated in a large number of conferences, both at home and abroad. The cinemotor outfits alone have illustrated addresses at 525 meetings, at which the audiences amounted to 160,108; 410,110 pamphlets have been distributed. This does not include the remainder of the work of the branches or any meetings not illustrated by films.

The Use of the Sigmoidoscope in the Diagnosis of Dysentery : A Clinical Lecture.

By Dr. A. J. GREGG, M.A., M.D., M.Ch., D.T.M. & H.,
Late Medical Superintendent,
Hospital for Tropical Diseases, London.

(A lecture given before the meeting of the Post-graduate Hostel, Imperial Hostel, Russell Square, London, W. C. 1, in September, 1926.)

Scope of paper.—While sensible of the honour of opening the discussion to-night, I am much exercised in mind as to what exactly is required of one opening an informal discussion such as this.

Should one deal in detail with one aspect of the subject, or treat it more widely and superficially; or should one deliberately try to provoke controversy?

I feel that I had best deal with the use of the sigmoidoscope in tropical diseases, speaking then from some little experience, and leave it to others to touch on different aspects of instrumentation.

As for provoking discussion, I am without alternative, for I feel sure, and, indeed, hope, that my few remarks will be obliterated in an avalanche of criticism.

Initial work.—My first serious acquaintance with the use of the sigmoidoscope was made in the Hospital for Tropical Diseases, London, and I desire to record at once my gratitude to the Honorary Staff of that hospital for their encouragement, and for permission to examine their patients.

In conjunction with Dr. Manson-Bahr, I have published an analysis of my first hundred examinations, which even then gave convincing evidence of the value of such examinations in obtaining accurate diagnoses. Indeed, it was because I had become thoroughly bored, not to say dissatisfied with innumerable microscopic searches for *E. histolytica* in the stools of patients suffering from "dysentery" that I looked around for some quicker method of diagnosis.

Value of Sigmoidoscopy.—My argument ran thus:—There are many causes of "dysentery," if we connote by this term any condition of tenesmus with blood and mucus passed *per rectum*, and, apart from cultural methods, the microscope can detect the casual organism only when the stool happens to come from a patient suffering from amœbic dysentery. Even then, granting the requisite skill, there are many limitations, for the *E. histolytica* is not to be found at every examination, not even in acute cases, as witness one patient passing frequent stools, mainly consisting of blood and mucus, in which amœbæ were found on the twenty-fifth day only, and that despite more than one stool examination daily by a skilled protozoologist. Again, if *E. histolytica* can be found when voided *per vias naturales* along with the intestinal content, would they not be the more readily found in a scraping taken from an actual amœbic ulcer? Lastly, who would think of treating a sore throat without so much as glancing at it. And believe me, the lesions of the bowel are no more difficult of macroscopic diagnosis than are those of the throat.

Value of the Microscope.—Please understand, however, that in no way do I decry the value of the microscope in this connection. I point out merely its limitations, and emphasise that it should be used as an adjuvant, but not as a substitute, for the sigmoidoscope.

Technique.—Passing now to the technique adopted, I find the following method of preparation to be as useful as any.

About two o'clock on the afternoon preceding the examination, the patient takes half an ounce of castor oil; next morning a soap and water enema is given, and the patient is allowed a light breakfast. One hour before the examination, the patient is given fifteen minims of tincture of opium. If necessary, the examination can be made with the patient in bed in the lateral position, but I prefer to have the patient on the table in the lithotomy position, as this posture permits any fluid content of the bowel to collect in the sacral curve of the rectum; such fluid can then be emptied out or swabbed out through the sigmoidoscope. The lithotomy position, too, appears to me to give the operator greater comfort of movement.

In cases of active dysentery of a severe nature, it is impossible to get the bowel quite clear; fortunately, in these cases the lesions are numerous and often characteristic, so that a mere transitory glimpse of a portion of the bowel wall will suffice for a diagnosis.

When ulcers are seen, my usual practice is to scrape an ulcerated surface here and there by means of a wooden match held in a long forceps. Such scrapings, smeared on a slide and covered with a slip, will often be found to be swarming with actively motile *E. histolytica*, even though previous examinations of the stools have been negative.

Normal Examination.—Before mentioning pathological lesions, I would like to describe the examination and appearance of a normal bowel.

The sphincteric tone should be good, with brisk anal reflex. No actual spasm should be present, nor should the preliminary digital examination (which should never

be omitted) cause pain. The sigmoidoscope is lubricated and inserted gently with the obturator *in situ* until the sphincters have been passed, when the obturator is exchanged for the light. Under vision the instrument is then advanced gently with the least possible use of the bellows.

The operation causes discomfort, but pain should be felt only momentarily when too great tension is being placed on the bowel, or when further progress is arrested. I greatly prefer to do the examination without an anæsthetic, because any complaint of pain is either of diagnostic import, or indicative of a danger point in the manipulation: it is rarely indeed that an anæsthetic is indicated. The bowel wall should be in soft folds which should gently yield as the instrument is advanced in the direction of the lumen. The mucosa should resemble the inside of the cheeks in colour, but slightly less shiny, and the small blood vessels are most prominent. There should be no abrupt change in the mucosa, but on reaching the pelvic colon the wall appears more flexible and the folds smaller and more numerous. Elevating the nose of the sigmoidoscope over the brim of the true pelvis may cause discomfort, especially when there is a large prostate, or any inflammatory condition of the uterus or its adnexæ. In quite a number of patients, examination cannot be carried beyond this point without causing undue discomfort; this often obtains even when everything appears, and probably is, quite normal.

Pathological conditions.—Turning now to the pathological bowels, I may say that the patients whom I examined were nearly all admitted to the hospital as suffering from "dysentery," nor, until after my examination, did I attempt to squeeze out of their histories any refinement of diagnosis as to the type of dysentery or the causal organism. Thus I was enabled to examine the bowels with an unbiased mind. In the majority of patients the dysentery proved to have one of three origins, helminthic, amœbic, or bacillary.

Of the helminthic variety there were but few examples; I have encountered dysentery due to infection with *Schistosoma mansoni*, and with *Heterophyes heterophyes*, but not in numbers sufficient to warrant my doing more than mention them.

The amœbic and bacillary types of dysentery I have seen in some three or four hundred bowels, and consider that a correct diagnosis between these two types can, and should be made; sometimes with fair probability, oftentimes with certainty.

The Amœbic Bowel.—In amœbic dysentery there are frequently accompanying hæmorrhoids; the sphincters are normal; the rectum is thrown into voluminous folds so that the bowel appears redundant. These folds are soft and easily pushed aside without pain. The colour and sheen of the bowel is normal; the contents, if present, are ill-mixed mucus and blood. Scattered on the bowel wall are small, clean-cut, oval, or diamond shaped ulcers, which may be covered by a grey slough, or present raw surfaces, which will be seen to bleed freely if rasped by the sigmoidoscope.

Whether the condition be acute or chronic, the appearance is little changed, except that the ulcers are more numerous and the blood more plentiful in the acute phase. Note that instrumentation is usually painless, despite the ulceration. A bowel of similar appearance may be encountered, but without any ulcers; a close inspection, however, will detect brighter spots on the mucosa, the sites of healed ulcers: such is the bowel of cured or latent amœbic dysentery.

The Bacillary Bowel.—In contrast with this is the appearance of the bowel in bacillary dysentery, both acute and chronic.

In the acute stage the sphincter may be hyper- or hypo-tonic; the bowel is intensely hyperæmic, and instrumentation is painful. The bowel content is a uniform mixture of blood and mucus with which much pus may be incorporated. The surface of the mucosa is dull, and oedematous thickening takes up the folds of the gut, so that they become less apparent. There may be large irregular, ulcerated areas, but not uncommonly

the bowel presents a spongy uniform wall, which oozes blood all over on the slightest touch.

In the chronic form of bacillary dysentery, the perineal muscles are wasted, the sphincteric tone poor, and the anus wellnigh patulous. The gut walls are thickened and firm, the folds narrow and scanty. The surface is, in part, normal or anæmic, in part hyperæmic and glazed or granular in appearance. There may be small ridges or polypi of spongy, granular consistency—a form of unhealthy granulations. Freedom of movement of the bowel in the pelvis is diminished, and instrumentation is painful.

Such are the sigmoidoscopic findings in bowels typical of amœbic and bacillary dysentery, and while atypical and border line appearances exist, a little practice will frequently permit of discrimination.

When both diseases are present, I have found that the bacillary appearances predominate.

There is always the chance of scraping any ulcers seen, and so, perhaps, confirming by microscopical examination the macroscopic diagnosis.

Mistaken Diagnoses.—As already stated, I made no attempt to define the nature of the patient's "dysentery" prior to the examination, and it is astonishing how many errors in diagnoses were then disclosed; errors, too, which could not have been detected by use of the microscope alone. Thus, labelled "dysentery," rectal cancer of many months' standing is, unfortunately, not infrequently found in patients coming from the tropics. I have also met with tuberculous ulceration and syphilitic stricture, ulcerative and hæmorrhagic colitis, polypi, and, commonest of all, hæmorrhoids.

Most of these patients' complaints could have been diagnosed on sigmoidoscopic examination; many by the use of a proctoscope; not a few by a simple digital examination; yet not one of these procedures, apparently, had been even attempted.

Truly, from time to time these patients had experienced dysenteric symptoms, but what negligence, indeed what criminality, lay in medical contentment, for months on end, in that travesty of a diagnosis—"dysentery."

Psychic Factors in General Disease.

Jour. American Med. Assoc., Vol. 89, No. 13, September 1927.

At the annual session of the American Medical Association in Washington, the relation of the nervous system to the human organism was considered in the light of recently acquired knowledge. The nervous system is divided functionally into several levels. Of these, the vegetative apparatus is the oldest in development; the cerebral cortex, the most recent, and between the two in point of evolution are the various reflex centres. The whole is united by association paths. Accordingly "it is not difficult," says Hunt, "to understand why mental states associated with anxiety, fear, depression, despair and prolonged conflict should cause disorders in other portions of the nervous system controlling visceral and somatic functions." Heart disorders, Foster points out, are accompanied by psychic abnormalities of two main types. In one type, genuine disease of the heart or blood vessels appears first and genuine mental disease follows. In the other type, primary mental disease is followed by misinterpreted sensations referable to the heart. The mental disease produced by cardiovascular disorders may be pronounced psychosis or merely a change in personality evidenced by diffidence and lack of initiative. The patient of the other class, in whom the mental condition is primary, often is trying to escape from a situation or from a conviction that is intolerable. His subconscious mind perceives that sickness would relieve him of responsibility, and current interest in heart disease supplies the needed suggestion. He then seeks medical advice for a visceral disease of which he is not a victim, but from which he sincerely believes himself to be in

danger. A large proportion of the patients seen in the course of an internist's practice are of this class. McLester believes that "one-third of the patients who come to the consultant because of digestive complaints are of the psychoneurotic type." He is convinced, furthermore, that most of them are not the victims of fortuitous circumstances but are born neurasthenics. In this respect it is encouraging to recall, with Hunt, that the constitutional factor does not necessarily exclude the possibility of adjustment and that well chosen environmental factors may offset the handicap of faulty inheritance.

In addition to the psychoneuroses that are associated with cardiovascular and gastro-intestinal disorders, well recognized psychic upsets may accompany exophthalmic goitre, diabetes mellitus and diseases of the nose and throat. The underlying cause of psychic events in these three conditions may be toxic neuroses, but as yet they cannot be placed definitely in that class. Neilson suggests that the chronic character of diseases of the nose and throat may bring on "all sorts of emotional and psychic upsets, ranging from simple phobias to stark terror." Difficulties in diagnosis and treatment of these conditions are further disadvantages from a psychogenic standpoint.

This review of the possibilities of psychic disorders in general disease demonstrates the truth of Woodyatt's assertion that "the power of emotions to produce physical alterations of the body does not seem unreal." Recognition and treatment of visceral and somatic symptoms which spring from mental causes, therefore, fall well within the field of the general practitioner and of the internist.

The Treatment of Burns.

By ALEXANDER MACLENNAN, M.B., C.M.,

British Med. Journ., October 1st, 1927, p. 590.

At the meeting of the British Medical Association in Edinburgh in July, MacLennan read an interesting paper on the treatment of burns. The first essential is relief of pain, and the speaker drew attention to the employment of prolonged chloroform administration as a substitute for morphia. The composition of the first dressing is important: wax solutions sprayed on the burned areas, waxed paper and tissue paper soaked in carbolic oil are recommended; a warning is issued against the toxic effects of picric acid when applied to large superficial burns. Shock should be treated by morphia and small doses of alcohol by mouth: fluid should be freely administered. There are obvious difficulties in the way of applying antiseptics to burned areas: most satisfactory results in this connexion are obtained by the use of horse serum but it is expensive. Duodenal ulcer as a complication of extensive burns has never been encountered by MacLennan. The importance of surgical intervention to prevent extensive scarring is emphasised. Thiersch or Wolff grafts cannot be employed until sepsis has ended: the speaker claims good results for his "tunnel" method of grafting. Narrow grafts are embedded under the surface and their locality marked by laying alongside them suture threads. After allowing for their taking root, which occurs in about ten days, the covering surface is removed so as to expose the grafts completely. On account of the close resemblance of the granulation tissue developed to sarcomatous tissue in its destructive effects a thin epithelial covering is almost certain of being destroyed from time to time. This feature of constantly recurring ulceration must be familiar to all; hence a solid covering is essential if healing is to be permanent. Scarlet red as an aid to epithelialization is recommended and we are reminded that burns can be caused not only by heat but by cold, chemicals, ultraviolet rays in sunlight, radium and x-rays.

Enemas: Some of their Uses and Abuses.

By LOUIS J. HIRSCHMAN.

Journ. American Med. Assoc., Vol. 89, No. 13,
September 1927.

THE employment of enemas has been rather overdone in recent years, almost any and every condition being subject to this treatment. The use of the soap-suds enema is condemned: following its use the mucous membrane becomes red and angry-looking and a plain water or 1 per cent. sodium bicarbonate solution is preferable. The use of hard rubber or glass enema tips or of the rectal tube is unhesitatingly disapproved of: Hirschman has seen severe laceration following the employment of one or other of these. A soft rubber catheter (No. 20 to 24 French scale) is the instrument of choice.

The ordinary urinary catheter having a conical tip and its aperture or eye just behind this on the side of the catheter adapts itself readily to the curvature of the anorectal canal. When well lubricated it is introduced with great ease and comfort to the patient, even right after operation. The outer end of the catheter can be slipped over the ordinary enema tip, which forms an excellent connector to the rubber tube connected with the enema container.

The type of lubricant used is of some importance. A water-soluble lubricant made of gum tragacanth or Iceland moss is the best. If the patient is not to be operated on there is no objection to the use of petroleum.

A greasy substance, however, is injurious to rubber and also makes it a little more difficult to cleanse the part before an operation. The same applies to olive oil or other like substances. Glycerin should never be used if there is any reason to suspect any raw surfaces or irritations. Nor should soap-suds be used, for the reason mentioned.

The lateral, or Sim's, position is the most convenient one for both the nurse and the patient in the administration of enemas. In this position, the parts can be seen and the weight of all the abdominal viscera is away from the lower bowel, so that there is no obstruction to easy entrance of the enema. If the patient lies in the lithotomy position with the knees fixed there is a tendency to strain and resist the enema which is absent when it is administered in either lateral position.

The attempt to give a so-called "high" enema is a futile proceeding as the rubber tubes simply coil themselves up in the rectal ampulla, and moreover the use of opaque enemas in radiographic studies of the colon has conclusively shown us that a pint of fluid will pass from the anal canal to the cecum often in one minute. This is as high an enema as any one could desire.

If the feces have become hard or impacted, hydrogen peroxide in the proportion of one part to two or three of warm water will disintegrate practically any impaction. Peroxide enemas are far more efficacious for removing an impaction than oil, glycerin or oxgall.

The use of turpentine to stimulate the expulsion of flatus is unnecessarily severe on the patient. One can secure far better results from the gentle astringent and stimulating effect of a 6 per cent. solution of powdered alum.

The flushing of the colon with gallons of water, either plain or medicated, has been greatly overdone in recent years. This large quantity of water not only distends the bowel but causes hyperemia and also removes all the mucus, which is nature's normal intestinal lubricant.

The legitimate field for enemas, irrigations and flushings is in the treatment of bacterial and parasitic diseases, e.g., colitis, proctitis, amebic dysentery or hæmorrhagic disturbances due to diabetic causes.

In some cases of multiple colonic polyposis a 6 per cent. enema of salicylic acid has produced a tanning

effect on the pedicles of small polyps, causing them to atrophy and be expelled.

Saline, alkaline or dextrose enemas are of great value in the treatment of acidosis, particularly of post-operative type. The rectal drip is, of course, a very valuable means of providing fluid in the postoperative care of serious surgical cases. There is really no good therapeutic reason for the employment of milk, molasses, starch and other kitchen necessities in enema solutions.

The use of the opaque enema containing barium or bismuth salts in the fluoroscopic examination of the colon is of course just as much a diagnostic standard as the use of the ophthalmoscope, stethoscope or proctoscope.

Before the use of enemas, irrigations or colonic flushes is resorted to in the treatment of what is apparently obstinate constipation, a fluoroscopic examination of the colon is advised. The observations in patients who have had pelvic or abdominal inflammatory conditions, stormy confinements or previous abdominal surgical operations will often point to definite adhesions causing obstipation.

The use of any sort of colonic flush in these cases will be merely palliative and of no permanent benefit to the patient. The use of watery solutions for cleansing the bowel has a distinct and valuable place in the practice of medicine. Enemas should be administered in a safe, careful and correct manner in order to be of the greatest value.

The present tendency in some quarters to run riot on the subject of colonic flushes should be checked, or the abuse of a well recognized procedure may leave behind a trail of woe which will take a long period of re-education to overcome.

Gold Therapy in Leprosy.

By F. C. EUBANAS and B. DE VERA.

Journ. Philippine Isl. Med. Assoc., Vol. VII, No. 9,
September 1927.

EUBANAS and DE VERA treated a number of moderately advanced cases of leprosy by intravenous injections of triphal and of krysolgan respectively: both are highly complex organic compounds of gold. The initial dose of the former preparation was 0.01 gram in 1 to 2 c.c. distilled water and of the latter 0.0001 gram in the same quantity of solvent. The injections were repeated at intervals of from a week to 10 days. The trial was a relatively short one owing to limited supplies of the preparations, but the results suggest that there is a certain slight beneficial effect on the course of the disease.

The Rai Sahib Shambhu Dayal Sahib - Gold Medal.

WE have been requested by the Director of Public Health, United Provinces to insert the following notice:—

A gold medal called the "Rai Sahib Shambhu Dayal Sahib Gold Medal" will be presented for the best prize essay on a public health subject to be announced each year.

2. The subject for the essay for 1928 is "How can the public best co-operate with the Public Health Department in the prevention of cholera in rural areas."

3. The competition will be open to the general public, including the medical, public health and educational men in the United Provinces.

4. The essay is to be written in Hindi and should not exceed 3,000 words in length.

5. The essay should reach the Director of Public Health, United Provinces, Lucknow by 1st May, 1928.

6. The name and address of the competitor must be distinctly written on each essay submitted, and the envelope should have the words "Prize Essay" in the top left hand corner.

7. The Director of Public Health, United Provinces, shall judge the merit of the essay and his decision with regard to the award of the medal shall be final.

8. No correspondence will be entered into on the subject of competition.

No essay will be returned.

Duties of the State in Relation to the Nation's Food Supply.*

By EDWARD MELLANBY, M.D. (Cantab.), F.R.S.,
Professor of Pharmacology, University of Sheffield,
Honorary Physician, Sheffield Royal Infirmary.
(*British Med. Journ.*, 8th October 1927, p. 633).

IN view of the great interest which is being aroused with regard to diets in India, a few extracts are given from this valuable paper.

State and local Government interference in matters of health, especially as it is affected by sanitation and drainage, water-supply, and limitation of spread of infectious diseases, is of benefit to the community. Is it likely that a similar interest in feeding will be followed by beneficial results of compensate order? Some may think not, but Dr. Mellanby speaking probably for all those in touch with modern work on nutrition held that the outcome of a sane and forceful effort on the part of imperial and local governing bodies in this field would lead to as revolutionary a change in the general health of the community as has followed their work on matters of public hygiene.

In a sense the problem of correct feeding is even of a more fundamental nature than that of general hygiene. When the diet is defective the most perfect hygiene as we know it will not prevent bad physical development, ill health, and early death.

The importance of vitamin-A in increasing the resistance of the animal to inflammatory conditions of the respiratory passages and lungs was alluded to as a forerunner of knowledge on the relationship between diet and resistance to infection. Purely metabolic disorders are brought about by incorrect diet; among these may be instanced the bone deformities and the defective dental structure and growth of jaws which follow deficient vitamin-D intake, the symptoms of scurvy due to deficient vitamin-C, the nervous symptoms due to deficient vitamin-B, the goitre due to deficient intake of iodine, the stunted growth due to deficient intake of biologically good proteins, and the ill effects of excessive and unbalanced cereals. These recently established facts are sufficiently important in themselves to justify the belief that it is a most profitable line along which the activities of the State should be directed and hastened.

With regard to research on nutritional problems, since the Medical Research Council was set up a large part of its activities have been directed to the solution of nutritional problems. It was a most happy occurrence for the progress of nutritional studies that the Medical Research Committee was appointed soon after the enunciation of the vitamin problem, and that Sir Frederick Gowland Hopkins, one of the original and present members played the leading part in this work.

The Medical Research Council has always been ready to support work on nutritional problems to the limit of its meagre resources. Unfortunately, its limited income is not the only drawback to rapid progress in this part of its work, for the field of workers upon which it can draw is very small. Work of this type does not attract young men, and even those who have

found themselves in this field have often arrived there by accident.

It is possible to foresee the end of this period of unpopularity, as even the scientist with the longest latent period cannot fail to be aroused by recent work on the antirachitic vitamin and its photosynthetic production by the action of ultra-violet radiations on ergosterol.

Dr. Mellanby went on to suggest that the following steps should be taken by the State in order to strengthen the control and executive power of the Ministry of Health in matters of nutrition:

1. That the Ministry of Health should set up a Board of Nutrition consisting largely of experts actively engaged in nutritional research, whose main duties would be: (a) to examine the results of the investigations carried out by those researching for the Medical Research Council, the Board of Agriculture, the Empire Marketing Board, and all others engaged in this field, both by studying their published work and, as far as possible, by personal contact with the actual investigations; (b) to advise the Ministry of Health to take action along lines which appeared to them advisable; (c) to recommend, or even to initiate, research on practical points where there is any obvious hiatus of evidence.

2. That the necessary authority be given to the Ministry of Health, acting on the recommendation of its Board of Nutrition, (a) to control the feeding of Poor Law institutions and prisons, and to advise in others, such as welfare centres or wherever public grants are made; (b) to publish authoritative statements, and, if necessary, give the evidence for such, on feeding matters to the general public; (c) to set up or control a food analysis department which includes not only the testing of food as at present carried out, but the standardizing of foods and other preparations for their vitamin content would be part of the duties of the Ministry of Health, acting on the advice of its Board of Nutrition. It is probable that official statements made to the press would be the most important method of teaching the facts to the average parent. At the present time this work is being attempted by several well meaning health societies, whose members have a strong conviction that diet is a very important subject, but whose knowledge of the facts is often lamentable.

The present method, which seems to be growing in popularity, of issuing manifestos to the press on dietetic subjects, is altogether wrong. These statements are often partisan in their origin and are frequently signed by men who, however distinguished they may be in their own lines, cannot possibly have any real knowledge of dietetics. The Board of Nutrition must supersede these well meaning efforts by better methods.

The maintenance, and increased facilities for obtaining special foods and the limitation, of others, is probably a line of action that may prove useful.

The trend of scientific work on nutrition is to divide foods roughly, from the point of view of disease, into three classes: (1) "protective" or disease-preventing foods; (2) harmful or disease-producing, or, probably better, "protection-demanding" foods; and (3) neutral foods. Among the first, or protective foods, would be placed milk, eggs, green and other vegetables, fruit, cheese, meat, and fat fish. In the second, or disease-producing foods, are cereals and cereal products, including bread of all kinds (white flour or wholemeal flour), maize, oatmeal, rye, rice. The third, or neutral group of foods, would probably include sugar, pulses (peas and beans), pork and bacon, and white fish. These are tentatively arranged, and it might be desirable with further knowledge to redistribute the members of group (3) among groups (1) and (2). For instance, the way in which sugar seems to upset experimentally fed dogs suggests that under some conditions it is a harmful food, and if there were any lack of vitamin-B in the diet pulses would then pass into group (1).

* A paper read in Section of Preventive Medicine at the Annual Meeting of the British Medical Association at Edinburgh, 1927.

among the protective foods. It may be necessary to point out that the inclusion of cereals and cereal products among the harmful foods does not mean that these substances are devoid of nutritional properties. They have many excellent qualities in this respect, and their harmful effects can be readily antagonized by some of the members of group (1), or protective foods. At the present time, however, a sufficiency of "protective" foods is often not eaten, and poor physical development and bad health result in many individuals.

In view of these facts it would be desirable for our hypothetical Board of Nutrition to consider whether it was necessary for the Ministry of Health to take steps to make the "protective" foods—milk, cheese, butter, eggs, fat, fish, etc.—more easily procurable by increasing the supplies. It would probably be undesirable at the present time to limit the quantities of the "harmful" group—that is, cereals—available, for these are the cheapest procurable foods and form the basis of the average diet in the country, and especially in view of the fact, as stated above, that they can be made innocuous.

This part of the problem involves a discussion as to whether it is desirable for the State (a) to play a greater part in the teaching of cookery, and (b) to provide means of cooking food for public consumption. Greater facilities for the teaching of cookery will be provided by local authorities as the demands for such by the public increases. Better education and greater realization of the importance of proper feeding will no doubt hasten this demand.

Pernicious Anæmia a Symptom-Complex rather than a disease.

By G. LOVELL GULLAND, C.M.G., M.D., F.R.C.P.
(Edin.),

*Professor of Medicine and Clinical Medicine,
University of Edinburgh.*

(*British Med. Journ.*, October 15, 1927, page 669.)

THE principal criteria are a high colour index, the presence of megalocytes, and, in the great majority of cases, leucopenia. Megaloblasts, if they can be found, are more helpful than usual. There may or may not be poikilocytosis, polychromasia, punctate basophilia, and other less important changes. We are all agreed that pernicious anæmia is essentially a toxæmia—a toxæmia which affects the blood and bone marrow more profoundly and more constantly than any other organ. The real problem is—what is the toxin? We do not know its nature. It is usually slow in action, gradually cumulative till its maximum effect is produced; if this is survived the patient recovers, sometimes very rapidly, either because the poison is exhausted or because a relative immunity is produced. Then the process begins again, and may be repeated several times. Can we accuse any known organism of causing the disease? The answer is, so far in the negative. There is no organism to be found in the blood itself. If a hæmolytic streptococcus were really the cause of pernicious anæmia we should expect and should find an entirely different series of blood changes. The same applies to the *Bacillus coli*, whose claims have also been mooted, with still greater force.

Moench, Kahn, and Torrey demonstrated that the fæces of 33 cases of pernicious anæmia contained a much higher number of *B. welchii* (and also *B. coli* and streptococci) than those of normal persons. Of these three organisms the only one really hæmolytic was the *B. welchii*. Kahn and Torrey have injected monkeys intravenously with *B. welchii* toxin in small doses, and claim to produce all the blood changes which are considered to be typical of pernicious anæmia.

It has been suggested that some spirochæte or protozoa might be responsible, but so far no definite evidence against either has been adduced.

Achlyia is practically constant but it is of frequent occurrence, not only among normal people, but in a host of debilitating conditions of the most various sorts.

One of the most striking facts about pernicious anæmia is that it does not develop out of an anæmia of low colour index, but, as far as I can judge, is primary in the sense that it is megaloblastic from the beginning.

Cryptogenetic or idiopathic pernicious anæmia is not the only form in which the disease occurs, but there are large groups of cases in which the cause is known, though we do not always know how the casual condition acts.

Bothriocephalus anæmia has a blood picture and symptoms identical with those of pernicious anæmia, and cure follows the removal of the worm.

A certain proportion of cases of sprue are also cases of pernicious anæmia.

Other groups of cases are those caused by syphilis and malaria, in both of which the marrow is probably primarily affected, and both of which can be cured by curing the original disease.

A different type is that associated with pregnancy. It is not very uncommon, and in my experience is not usually fatal, though it may be so.

Another condition which can produce the blood picture of pernicious anæmia is over-radiation.

The sum of all this is that there are many conditions, known and unknown, which can produce a megaloblastic anæmia; that we cannot hope to discover the cause of pernicious anæmia, because there are many causes. In other words, pernicious anæmia is a symptom-complex rather than a disease.

The treatment of pernicious anæmia is unsatisfactory, from the point of view of ultimate cure, but it is possible to do a great deal for these cases, and it is most important to approach treatment in a hopeful spirit. Nearly 100 per cent. recover, or should recover, from a first attack; the great majority will from a second. It is in the later relapses that real difficulty arises, and that our therapeutic resources are tested.

Rest, sunlight, fresh air, cheerful surroundings, general tonic measures, are important. Diet requires to be regulated by the patient's alimentary condition, and has to vary between the severe simplicity of peptonized milk in cases with much sickness, and a practically full diet when the stomach is not disturbed.

Hydrochloric acid is used as a routine measure, in medium doses it certainly helps appetite and improves digestion; but the huge doses that Hurst would have us use are not well borne. In cases associated with severe gastric catarrh the acid is not tolerated at all, and one has to fall back on ordinary sedative measures.

Arsenic remains our standby, and the best way of giving it is as the hydrochloric solution by the mouth, gradually increasing the dose till the patient's limit of tolerance is ascertained, and continuing with the largest dose that can be taken with complete freedom from arsenical symptoms until in favourable case a colour index below unity is attained. It should then be stopped and iron given instead. Cases recovered more quickly with arsenic by the mouth than if it given intravenously or intramuscularly, either in simple solution or as the organic arsenics.

Transfusion of blood is not curative, is sometimes not even useful but may be of great service in helping the patient round a critical corner when his vitality is exhausted by toxæmia, and may give him a chance to recover himself.

Normal horse serum, given either intramuscularly or by the mouth, sometimes seems to be of service when arsenic fails.

Intestinal antiseptics are not curative, but are often useful as adjuvants.

In no disease is it more difficult to estimate the effect of treatment, unless one has dealt with large series of cases, because of the tendency to remission which may come on at any moment without warning, and without cause. A recent case impressed this on me afresh.

Dramatic recoveries are more common in first and second attacks, but may occur even with later ones. One is inclined, therefore, to be sceptical about the result of any new line of treatment unless a large number of cases have been dealt with, and it has been found to be as useful in late attacks as in early ones.

Treatment of Pernicious (Addisonian) Anæmia with a Diet Rich in Liver.

By GEORGE R. MINOT, M.D.,
and

WILLIAM P. MURPHY, M.D.,

(*British Med. Journ.*, October 15, 1927, p. 674).

ONE hundred and twenty-five patients have been treated with the liver diet for from three months to three and a half years. The health of all has been distinctly improved. Not only has nearly every one of the patients responded promptly to the liver diet, but if they have continued to take it satisfactorily their red blood cell count has remained elevated, and in almost all instances above 4 million, and usually above 4.5 million, per cubic millimetre.

After feeding with large amounts of liver there occurs with extraordinary regularity a prompt temporary, often marked, increase of the young red blood cells (reticulocytes). This behaviour of the reticulocytes also suggests that liver stimulates the maturation of the megaloblasts.

Dr. Edwin J. Cohn has isolated an effective fraction, which represents about 1 per cent. of the liver. It contains nitrogen, but is non-protein in nature, is precipitated by alcohol, and soluble in water. The indications at present are that its effect is not due to known vitamins. A few grams of the purest fraction taken daily by mouth as a powder or in an aqueous solution is followed by a prompt and marked increase of reticulocytes and a rapid rise of the red blood corpuscles, and in a similar manner is as beneficial to patients with pernicious anæmia as whole liver.

Table showing the Rate of Increase of the Corpuscles for all of the 108 of the 125 Patients whose Red Blood Cells were below 2.7 million per cubic millimetre when they were first placed on the Liver Diet—no matter whether they took it well or poorly.

Time of Observation.	Average Red Blood Cell Count in millions per cubic millimetre.
Before diet begun	1.50
After diet taken about one month	3.36
After diet taken about two months	4.25
After diet taken from four to six months.	4.65

Failure to take a sufficient amount of liver or the presence of a complication, such as an infectious process, may cause the count to fall, or may cause it to rise less rapidly than might be expected. Damage to the bone marrow from multiple transfusions of blood may be a reason for an unsatisfactory response to liver feeding.

The health of six patients whose counts have not reached 4 million per cubic millimetre has been distinctly improved.

At the end of a year the average red blood cell count for all of the 60 patients who have taken the diet for this length of time was 4.52 million per cubic millimetre.

Eighteen of the patients have taken the diet for two years or longer, 3 of whom have done so for three years. At two years the average count was 4.65 and at three years 4.81 million per cubic millimetre. These high average counts have been persistently maintained, and the average for the patients who have taken the diet particularly satisfactorily is even higher.

As a rule the patients have felt and appeared well, except for disorders of the central nervous system, two months after starting the diet. The appetite has improved rapidly and often become ravenous. Gastro-intestinal symptoms have decreased quickly. Tongue symptoms usually vanished soon after liver was first taken and have not recurred in patients who have continued to take the diet well. The tongue has frequently become normal in appearance. Achlorhydria, however, has persisted in the 20 cases examined. Symptoms referable to the neural system have not definitely progressed or developed under adequate dietary therapy.

It will require often much time, tact, and sympathy to persuade the patient to take the correct food. Giving little other food than liver—by stomach tube, if necessary—has enabled individuals soon to take the full amount (150 to 225 grams cooked weight) and an adequate diet. Patients able to take more than 200 grams of liver a day may regain health faster than if less than this amount is taken. Cooked liver may be served in any way that pleases the patient, but prolonged boiling is to be avoided. The broth in large amounts is efficacious. Raw liver served as a finely divided pulp has been found particularly suitable. Many patients have preferred this to cooked liver because it is simple to take and can be swallowed rapidly. One hundred and eighty grams of the pulp (about equal to a similar amount of cooked liver) a day, divided into two portions, and taken mixed with orange juice or water mid-morning and mid-afternoon, is recommended.

It is advised that the diet be rich in fruits and greener vegetables and that it contain red meat.

It is desirable to curtail sweet foods and those rich in starch.

Reviews.

MALARIA IN INDIA.—By Major-General Sir Patrick Hehir, K.C.I.E., C.B., C.M.G., M.D., I.M.S. (Retd.). London: Oxford University Press, 1927. Pp. 490. With 115 colour plates and 109 figures. Price, 42s. net.

THIS splendid volume should be in every medical library in India, whilst it will interest every malarialogist in the country. The author's very distinguished career in India and during the Great War is well known; and now, in the leisure of his retirement, he has found time to put together this excellent symposium. The volume is much more than a second edition of the author's *Prophylaxis of Malaria in India* (1910); it is a complete and comprehensive memoir dealing with every possible aspect of the problem of malaria in India, and the amount of industry which must have gone into its making is amazing.

In a way, it is a pity that there is not more original matter in the book. During the War the author lost two large boxes of manuscript intended for this book and many hundreds of maps, plans, photographs, etc. In consequence the book is largely a compilation from many different sources. Thus the colour plates of the malaria parasites are from Byam and Archibald's *Practice of Medicine in the Tropics*, and Stephens and Christophers' *Practical Study of Malaria*; those of the anophelines of India—and very admirable they are too—are chiefly from Byam and Archibald's work, and

James and Liston's *Anopheline Mosquitoes of India*; the photographs of mosquito breeding sites and of anti-malarial measures are largely after Malcolm Watson's *Prevention of Malaria in the Federated Malay States*, with diagrams from Hardenburg's *Mosquito Eradication*; and the temperature charts from Manson-Bahr's *Tropical Diseases*. Yet even in this particular point, the author has rendered a very great service to the medical profession in India, for the collection together under one cover of all this valuable and excellent material gives the reader a volume which is at once comprehensive and authoritative. If there is—indeed—one word in which we should like to sum up the book it is in the adjective "comprehensive"; for that most adequately describes it.

The volume commences with a brief account of the history of malaria, which mentions the outstanding points, such as the discovery of cinchona febrifuge, the discovery of the malaria parasites by Laveran, of mosquito transmission by Sir Ronald Ross, and of the introduction of the Romanowsky stains, and other matters. Thereafter the book is divided into three main parts as follows:—

Part I.—The endemiology, epidemiology, and ætiology of malaria in India.

Part II.—Clinical and pathological effects of malaria in India.

Part III.—Methods of prevention of malaria in India; followed by appendices, one of the most important of which deals with new knowledge on the subject which has been published while the present volume was in press. Thus the work is absolutely up to date, and contains much of the 1926-1927 literature. Christophers and Sinton's malaria map of India is also included; indeed from Appendix II we learn that this map was originally prepared for this book. The author has also borrowed largely from that invaluable fund of information, the *Annual Reports of the Public Health Commissioner with the Government of India*.

Throughout the book the author rightly stresses the economic importance of malaria, for this is the gist of the whole matter. At least a million deaths a year occur in India from malaria—probably more nearly a million and a half; whilst the amount of sickness, morbidity, and loss of labour which the disease causes is incalculable. "For some years to come," writes Sir Patrick, "the use of these drugs (the cinchona products) can only have a partial effect on the reduction of malaria in India, as at the present time not more than 10 to 15 per cent. of the cases of malarial infection occurring there are treated by quinine or cinchona febrifuge, and it will be many years before the latter drug can be manufactured at apiece that the masses can meet.....I have also deemed it obligatory to deal with the bearings of the economic and sociological conditions of the masses of India on the reduction of malaria; frankness and conviction demand this, as these subjects are probably more important than the preventive measures detailed in the text. These measures, if properly carried out, can very materially reduce the malaria among the educated classes living in satisfactory economic, hygienic and social conditions, but they are at present beyond the education, comprehension and the means of the *unaided* rural masses; these masses preponderate incomparably over the well-to-do." And the author on page 426 discusses the question of the possibilities of a malaria tax. We regret that we have to agree with him; not until a very small malaria tax is levied—to be spent entirely on anti-malaria measures—will it be really possible to face the malaria problem in India on a suitable scale. "Millions die in the attempts to acquire immunity, chiefly children, while those who do acquire it go through years of suffering, and for the time being are wrecks of childhood and manhood. It is the work of the statesman, anti-malarial sanitarian, and especially of the educated and better-class Indian and landowner, to eliminate the suffering experienced in the immunising process, and to help the people to acquire immunity

through healthy environment, better houses, and better food." And here we are glad to note the emphasis which the author lays on anti-mosquito measures; for the recent report by the Malaria Commission of the League of Nations on the control of malaria in Southern Europe, in our opinion, has laid too much stress on quinine-prophylaxis, and we do not believe that quinine-prophylaxis is going to eradicate the malaria of India. It is the mosquito which counts most, and every area requires local investigation and survey. Pages 429 to 435, which deal with the economic and sociological questions connected with malaria in India, we consider to be the most important in the whole volume; they at least are original and forceful writing, and very much to the point. "Bonification" may not be the secret of malaria control, yet in many countries such bonification has produced a condition of anophelism without malaria.

To turn to the main body of the book, Part I is subdivided into eleven different sections; and in turn the author deals fully with the prevalence of malaria in India; the mortality due to it; its geographical distribution; contributory causes; predisposing personal causes; immunity or tolerance; the rôle of man in the distribution of the disease in India; epidemic malaria in India; the human carrier; and the Indian anophelines. This last section is extremely complete; it includes full synoptic keys after Christophers, dealing with both adults and larvæ; and a most valuable twenty pages devoted to the bionomics of Indian anophelines. The laboratory study of malaria is then fully dealt with, and we are especially glad to note how detailed is the account given of laboratory technique. In one respect we disagree with the author with regard to Leishman's stain. In the experience of the reviewer this stain should be poured over the slide, left on for half a minute only—(one minute is too long); and *double* the amount of distilled water added. To leave the undiluted stain on for one minute and only add an equal volume of distilled water is to invite a deposit of stain on the slide, under usual *tropical* conditions. Theories as to relapses, and such matters as culture of the malaria parasites are here dealt with.

Part II is essentially clinical, and is excellent. Here in turn the symptomatology of malaria is very fully dealt with, and—a specially useful section—the relationship of malaria to other infectious diseases, where the association of malaria and sunstroke is brought out. The pathology of malaria—clinical, chemical, and histological—is then dealt with; followed by a chapter on treatment, a section which we consider might be considerably expanded in a second edition, as it only occupies four pages.

Part III comprises the main section of the book and deals very fully with malaria control. Here, again, the very comprehensive character of the volume is very apparent. The use of the cinchona alkaloids is dealt with in detail, and we are glad to note that the author condemns intramuscular quinine—or at least mentions the ill-effects which may result from it—as do most leading authorities. Messrs. Howards have contributed to this section of the book, and the pharmacological notes on the cinchona alkaloids which it contains will be very useful to many workers in India. In Section 3 of this part, the author next takes up the question of mosquito control in India. Here, in 66 pages, we have a complete and very well illustrated memoir on the whole subject—drawn from many different sources, and admirably illustrated.

Section 4 of Part III deals with the prevention of malaria in human habitations in India, and deals respectively with cities and towns, villages, schools, houses, labour organisations, military cantonments—a chapter which is especially informative, and which includes much original matter from the author's own pen, as he has had much experience in this matter—in jails, and individual prophylaxis. Administrative problems in connection with malaria are next considered, and then finally come the appendices. These deal with

malaria statistics for India in 1924; the malaria map of India—an account from Christophers and Sinton; anti-mosquito legislation; a popular leaflet for propaganda work in connection with malaria; a malaria survey questionnaire; and very recently published new work on malaria. The volume is well indexed, the index occupying 25 pages.

It only remains to add that the work is most admirably published, and well up to the very high standard of the Oxford University Press. The reproduction of the colour plates is altogether admirable. Glazed art paper is used throughout, and the volume is of convenient size and form. (One point—however—we may perhaps be permitted to bring to the notice of the publishers, and of other publishers at Home who publish books for sale in the tropics. This is that cockroaches in the tropics immediately attack all books printed in the United Kingdom. In the tropics, we understand that it is usual to incorporate a certain amount of bluestone in the paste used for binding, as this defeats the attacks of cockroaches and "fish-insects." The review copy of this book which we received, although brand new, is already cockroach-eaten, whilst a copy of Wenyon's *Protozoology*, received in August 1926, already looks moth-eaten, although in daily use.).

Sir Patrick Hehir and the Oxford University Press are both to be warmly congratulated on the publication of this book. It will be invaluable to malarial workers and public health authorities in India, and—we hope—in constant demand. It gathers together in compact—and admirably illustrated form—the whole of the literature on the subject. It is especially noteworthy for the tremendous amount of detailed information and illustrations which the author has collected together within the compass of a conveniently-sized and eminently readable volume.

MODERN MEDICINE: ITS THEORY AND PRACTICE.
—Edited by the late Sir William Osler, Bart., M.D., F.R.S. and Thomas McCrae, M.D. Vol. V. Third Edition. London: Henry Kimpton, 1927. Pp. x plus 948. Illustrated. Sold only in sets. Price, £12-12 per set.

VOLUME V of Osler and McCrae's *Modern Medicine* is divided into six parts dealing respectively with diseases of the blood, diseases of the lymphatic system, diseases of the ductless glands, diseases of the urinary system, vasomotor and trophic disorders and diseases of the locomotor system, comprising the combined labours of nineteen contributors. Criticism is almost superfluous: Osler and McCrae's work ranks with Allbutt and Rolleston's system as one of the standard sources of reference on matters medical, and the present edition (so far as the volume under review is concerned), does not fall short of the traditional excellence. Each subject is dealt with in a thoroughly complete manner by an acknowledged master in the particular field concerned; all the recent advances are referred to. In a rapid but fairly complete survey of the work we were particularly impressed by the following:—The physiology of the pituitary gland. This is one of the most complete expositions of the whole subject that we have been privileged to read. The treatment of exophthalmic goitre, one of the most fruitful subjects for debate between physicians, surgeons and radiologists, is dealt with in a clear and impartial manner. The section on diseases of the urinary system: there is an admirably fair presentation of the conflicting views on urinary secretion, and in connection with nephritis there is a timely warning against trying to predict the pathological state of the kidney from the clinical signs and symptoms presented by the patient.

There are one or five very minor blemishes which we hope will be removed in future editions. In page 23 the reader is referred to Plate III, Figs. 1 and 2 MA for a view of "mast" cells. This should be Plate IV, Figs. 1 and 2 MA. On page 48, reference is made to 2,000,000 red corpuscles per cubic centimetre instead

of per cubic millimetre, and on the following page the same error is most unfortunately repeated twice.

There is an error of exactly similar type (in connection with blood platelets) at the foot of page 114. On page 71 line 7, "as an acute sepsis" should be as *in* acute sepsis" while on page 289 "specific strains" should read "specific stains"; we suggest "propionic acid" for "profrionic acid" on page 322. In a lesser work such errors, (largely we believe attributable to the printing room), might have been passed without comment, but occurring in *Modern Medicine* we feel that they detract from its otherwise supreme excellence.

J. M. H.

PREVENTIVE MEDICINE AND HYGIENE.—By Milton J. Rosenau. Fifth Edition. New York and London: D. Appleton & Co., 1927. Pp. xxv plus 1458. Illustrated. Price, 42s. net.

THERE are many good books on public health but few wise ones; Rosenau's is to be classed as both. "Knowledge comes but wisdom lingers" is a trite saying, truer as regards preventive medicine than many other things. In the past twenty years it has been recognised by sanitarians that good environmental conditions, though absolutely essential for maintaining good health, are really not so fundamentally connected with the improvement of the human race as we thought. Good human protoplasm nurtured in a good environment is what is wanted, and we are only beginning to have glimmerings of how to attain this. In this respect one generation is the custodian of the next, and the unborn have the right to demand and expect that best of all birthrights—good human protoplasm. Hence it is that heredity and eugenics find a place in the modern public health textbook; and the sanitarian (in the wide sense) who would be up in his subject must have more than a nodding acquaintance with psycho-analysis and mental hygiene. Amid the swaying controversies that surround the study of heredity, one fact shines out which the everyman of to-day should know, that the germ plasm entrusted to man and woman is the most precious substance known, that to pass it on to the next generation in as good or better a condition than that in which it was received is a duty, but to pass it on in a damaged condition is a crime which no fabled circle of the Inferno could ever expiate. Injury to the germ cell is irreparable and transmissible. But Nature's methods are sometimes insatiable. The race is not always to the swift nor the battle to the strong. Degenerates and defectives have little self control and are very prolific. In England the feeble minded are increasing at twice the rate of the general population. Feeble mindedness produces more pauperism, degeneracy and crime than any other cause; it touches every form of charitable activity; its cost to the State (that is to the ordinary individual) is enormous.

Heredity is the overshadowing influence of first and prime importance. Environment may influence the individual, but apparently has small and slow power of propagating itself for good; great and rapid power for evil. But Nature and nurture "heredity and environment" all play important rôles in the final moulding of the individual body and mind. The sensible attitude is to be concerned with progeny rather than with ancestry, and to continue the struggle for betterment.

The chapter on "Mental Hygiene" by Abraham Myerson is well worth reading; and everyone should understand the elementary psychology of the introvert and the extrovert, and should read the paragraphs on the upbringing of children. We believe it pardonable to quote *in extenso* from the paragraph on desire and satisfaction—The laws of normal desire and satisfaction will some day constitute the basis of a programme of mental hygiene. We know that civilization enormously complicates what we call our needs, so that the luxury of one time is the absolute necessity of another. The rise of æstheticism breeds hyperæstheticism; which really means that those so afflicted find

many more things to disgust and dissatisfy than to please them. Refinement brings it about that one finds a subtle pleasure in the very nice adjustment of things, but also it brings about the little disharmonies are keenly felt, and the pinpricks of life become tragedies. The mounting of desire and taste is a part of civilization, yet it is a part fraught with neurasthenia and an anhedonic reaction to life; that is, a reaction of lost desire and satisfaction. Simplicity of taste, robustness of satisfaction—to maintain these is to maintain happiness and mental health. And the formula for maintaining them is not easy to find and harder to follow in a competitive world where people measure the value of what they have by a comparison with the acquisitions of others. If we could get a real picture of the inner life of men and women of a striving, civilised community, we would find in it an appalling amount of heartache and dissatisfaction, bred by envy and jealousy of others. The struggle for existence, tense as it naturally is in our industrial civilization, is intensified a hundredfold by a struggle for superiority in things which are of no real value. This struggle breeds fatigue, disgust, and depression. Its only cure is a philosophy of life which has been preached at mankind from time immemorial, but which is difficult to follow, though all men theoretically accept it. 'Thou shalt not covet' is its essence, however, amplified it may be.

When a man commences to find that his desires are finicky and his satisfactions vague, when appetite for food, sex, sleep, commence to disappear, when he is as fatigued in the morning as when he went to bed, when the pleasure of work and play become difficult to obtain, it is time for him to take stock of himself and his habits of life. Changes in mood and feeling are as important and need attention as much as shortness of breath and indigestion."

The chapter on water is very good; that on sewage disposal hardly full enough for English requirements. English plumbing is different from American, and the diagrams in this chapter would certainly be criticised in England. Air and ventilation are clearly dealt with, though English works on this (Hill's for example) are rather scrappily discussed. Estimations of comfort in our opinion are more easily and more simply carried out by the *kata thermometer* than by the *effective temperature chart* process.

The chapters on vital statistics and statistical methods are not by Rosenau. It is a pity he did not get his late friend Whipple to do these chapters. The former is not detailed enough, and the latter is much too compressed.

Tropical matters are dealt with quite well, though we do not agree that *A. sinensis* is the chief malarial carrier in India, or that bedbugs carry European relapsing fever. The work on *Leishmania donovani* by Knowles, Napier and Smith, with *Phlebotomus argentipes* is noticed; the pentavalent antimony compounds for treatment however are not mentioned.

Perhaps not a perfect textbook for every climate and country, but a very stimulating one and a pleasure to read. No one interested in preventive medicine and hygiene can afford not to have the latest edition of "Rosenau" on his table.

Perhaps it is rather premature, but we would like to see in the next edition the chapters on "The Newer Epidemiology" developed on the lines of the work of Topley and others.

HYGIENE AND SANITATION: THE ESSENTIALS OF MODERN HEALTH CARE.—By Jesse F. Williams, M.D. London and Philadelphia: W. B. Saunders Company, Ltd., 1927. Illustrated. Pp. 344. Price, 10s. net.

THE American nation at the present time is probably the most favoured of all. Her geographical position gives her a freedom from many of the world's worries; her natural resources and vast territories and immense wealth secure for her a freedom or at least a remote-

ness from these international jealousies and a postponement of these difficulties, generally called Malthusian, which have involved European nations oftentimes in war and disaster.

With the world's history behind them, and with knowledge, wealth and experience in their grasp, it is natural that thoughtful Americans should be considering whether as a nation they are making the most of their opportunities. The present book is intended to present the fundamentals of health and personal hygiene in a manner suitable for teacher and student. The essentials for obtaining and maintaining personal health are clearly and interestingly stated, and the necessity for both knowledge and practice insisted on. There are chapters on all the seven ages of man, and on the eighth that Shakespeare missed out, the prenatal stage; and mental hygiene is very sensibly discussed and explained.

A style of sentimental optimism is rather common in American writers on health matters. When we had read a little of this book we said to ourselves, *Mens sana in corpore sano* is of course bound to appear soon, but can the author withstand the temptation of *God's in His Heaven, all's right with the world*? Page 66 gave us the one and page 88 the other. *The child is father to the man* is quoted as an old saying, but we like to think that *the child is father of the man* was penned for the first time by Wordsworth. Has Roosevelt so soon earned the title "immortal"?

We recommend the book as an admirable and sensible presentation of what health is and how to obtain and retain it.

A. D. S.

AN INTRODUCTION TO NEUROLOGY.—By C. Judson Herrick. Fourth Edition. London and Philadelphia: W. B. Saunders and Co., Ltd., 1927. Pp. 406. Illustrated. Price, 12s. 6d.

THERE can be no doubt that neurology is now established as an important subject in biological science. Here we have a work of 400 pages, and yet it but merits the title of an introduction. This indeed shows the vastness, as well as the importance of the subject. Professor Herrick presents us with the fundamental facts of neurological science in a manner which is as simple as possible.

The book is divided into three main divisions. The first of these discusses the more general neurological topics; such as "the nervous functions" and "the reflex circuits." These matters are dealt with in a general way, and not only from the limited aspect of the human body.

The second part describes the general anatomy and physiology of the nervous system. This description again is of a comparative nature, and is well illustrated with diagrams showing the anatomical relations, both of the human system and those of many of the lower animals.

A chapter on pain and pleasure from the physiological aspect is of particular interest.

The third part is devoted to the cerebral cortex and its functions.

There is a most extensive bibliography, and this is arranged after each chapter.

It must be understood that this book is not in any way a book on nervous diseases. It is rather an introduction to neurology in its much wider sense.

It is difficult to imagine that it would be useful to the medical student in India, who is already overburdened with "ologies."

That it has reached a fourth edition is evidence of its value, but in India we have not yet students who take advanced courses in the various subdivisions of anatomy and physiology.

H. H.

HOW TO MAKE THE PERIODIC HEALTH EXAMINATION.—By E. L. Fisk, M.D. and J. R. Crawford, M.D. New York: The Macmillan Company, 1927. Pp. 393, with illustrations.

THIS is an excellent book with an inadequate title, for it really amounts to a textbook of routine clinical

methods. The authors, having pointed out the importance of the periodic health examination in the preface and introduction, continue with a detailed description of the methods that should be employed.

The first section emphasises the importance of accurate histories and thorough examination, and includes specimen forms for the recording of results.

These forms are a great deal more complicated and cover far more ground than the medical forms of the most exacting American insurance company.

They rather appal the reviewer. The medical examination form includes, besides ordinary clinical examination, a full *schema* for the examination of the eye; focal errors, muscle balance, optic disc (with chart). This is followed by a fairly complete examination of the nose and ear. Next the teeth, and the form includes a dental chart with fifteen different possible defects for each tooth.

The clinical examination follows the ordinary routine and is most thorough. The space to be filled in under genito-urinary system includes penis, urethra, testicles, epididymis, seminal vesicles and prostate, the last having six subdivisions.

In the introduction it is stated that this examination can be carried out in one hour, and that specialists are only required in borderline cases. This may be so in America, but the reviewer must confess that he knows of no medical man who would carry out all these examinations in such a way that he would recognise early pathological changes, which after all is the main reason for periodic examination. The greater part of the book is devoted to a description of the methods of regional examination. This is really excellent and amounts to a detailed account of how to carry out the clinical examination of each part of the body. Each section is preceded by an introduction by a specialist, and in these introductions we learn the reasons why the examinations of each particular part is of importance. The various sections are admirable and the methods of examination are very fully described. We find that on looking at the protruded tongue ten points are to be noted. The chapter on the circulatory system is perhaps the best, and the authors insist on the importance of electro-cardiographic examination in doubtful cases.

It is likely that in the examination of presumably healthy people of mature age, we shall find a defect in kidney function more often than a defect in any other organ. It seems to the reviewer that this is not sufficiently emphasised in the chapter on the urological system.

The section on laboratory methods and standards is very valuable. It includes all the more important examinations. The technique of the methods is not of course within the scope of this book, but we have not seen the indications for, or the interpretations of the examination results better described elsewhere.

There is a chapter entitled "Counselling." This is of course the advice that should be given to the patient as a result of the examination. But the chapter contains more than this. Explanations of the methods of dieting, exercise and mental hygiene find a place. We are glad to see that the "Counselling" includes a letter and report to the patient's family physician.

An appendix contains many specimen charts and forms. These are all interesting, but in some cases seem rather complicated.

We all know in India the "complete urine analysis form," but here we have similar forms for many other examinations that are becoming commonplace. Gastric analysis, basal metabolism test, x-ray examination of the heart and aorta are a few out of many. It seems desirable that such reports should be given to the physician on a standard form. There is a full bibliography and an index.

It is difficult to assess the value of this book to practitioners in this country, for it will be many years before such periodic examination can be carried out in this manner in India. But here the information is not confined to the routine of such procedure only, for we

learn the best methods of conducting the examination of any of our patients, whatever may be their complaint. More particularly are we shown the indications for the more complicated methods which modern science demands, and the interpretation of the results. This book must prove invaluable to the intelligent student, for if he follows the procedure laid down his work must become methodical and logical.

The practitioner, also, will always find in it much of value. A study of the methods of examination advocated should save much time that is at present wasted, owing to haphazard methods of investigation.

H. H.

RESEARCHES IN POLYNESIA AND MELANESIA: AN ACCOUNT OF INVESTIGATIONS IN SAMOA, TONGA, THE ELLICE GROUP AND THE NEW HEBRIDES IN 1924-25. PARTS I-IV, MEDICAL ENTOMOLOGY.—By P. A. Buxton, M.R.C.S., D.T.M. & H. London: Published by the London School of Hygiene and Tropical Medicine, 1927. Pp. 260, with 12 plates. Price, 10s. 6d.

THE volume under review forms Part I of the results of an expedition to study filariasis in the Islands of the Pacific, and is devoted to the entomological side of the problem. In addition to this, there is a short account of the malaria problem of the New Hebrides group, the depopulation of which has already been treated of by the same author in a most interesting paper elsewhere (*Trans. Roy. Soc. Trop. Med. Hyg.*, XIX, 420-454), and a short account of the general medical entomology of the region.

Let it be said at once that the investigation is a model of what such should be. In the first place the relationship of the two carrier species, *Aedes (Stegomyia) variegatus* Doleschall, and *Aedes (Stegomyia) argentea* Poiret, *fasciata* Fab. is shown to the rest of the Culicine fauna and to the topography of the Islands. Thereafter the field biology of the two species is studied in detail. The second half of the book is then devoted to a series of carefully designed experiments to elucidate individual points in the bionomics of the two species.

Once again hydrogen ion concentration is shown not to be a natural controlling factor, though gross experimental differences are effective. As careful a study of meteorological conditions as is possible, outside a fully equipped observatory, shows that no climatic factor, or even the differences in the amount of radiant heat received from the sun at different seasons, affects the insects. But, in the reviewer's opinion, this conclusion is not universally applicable. The variations recorded in all factors are small, as would be expected on an oceanic island within the tropics, and the portable "Radiation Integrator in vacuo" evolved by the author, which can be used by workers other than trained physicists, should prove an extremely valuable weapon in climates with greater ranges, where one of the factors most requiring measurement is the number of units of heat absorbed by different bodies of water from the commencement of the spring temperature rise.

Turning to the actual experimental work, all investigators should well ponder the five "conditions of experiment" laid down on pages 127-8. After indicating that some experiments which now appear effectively controlled are not, owing to the impossibility of controlling any factor imperceptible to man but of great importance to the mosquito, and showing that through neglect of obvious precautions much of the already large accumulation of experimental results obtained for *Stegomyia fasciata* must be rejected, there follows the thought-compelling statement, "when, therefore, an experiment has led to a definite conclusion, one should devise a second experiment which does not exactly repeat the conditions of the first, but has the same conclusion in view." One wonders how many experiments, of one's own and of others, have been falsified on account of the omission or impracticability of applying such a double

test. Mental discomfort as to the validity of results makes for progress.

There follows a mass of experimental detail on the factors possibly affecting oviposition, hatching, and the existence of larvæ and pupæ, which there is no object in categorically stating in a review. All interested must consult the original for themselves. However, the main conclusion reached is that "the large amount of experimental work.....performed has on the whole added to the pre-existing confusion." In making this statement, the authors have most unduly belittled their own work. If definite results are few [and from this work has come the re-discovery of the method of inducing oviposition in fluids immediately fatal to the emerging larvæ, which the author has already published as "Race Suicide in *Stegomyia*" (*Bull. Entom. Res.*, XVI, 151-3)], they have at least cleared the ground of any fallacies introduced by previous experimenters, and set forth a series of definite and properly controlled results. That these as yet elucidate nothing completely is certainly disappointing, but none the less stimulating. The ground has been cleared for further and more intensive effort. With every advance, it is true, the complexity of the problem becomes more apparent, but there is no need to despair. That the solution is there is certain, and as a fellow worker on the same problem the reviewer emphatically states that the present series of results will afford matter for consultation and comparison for years to come. As pointed out by the author, the problem of *Aedes* are the problems of *Anopheles*, the most important aspect of all medical entomology, in a simpler form.

R. S-W.

THE OPERATIONS OF SURGERY.—By R. P. Rowlands, O.B.E., M.S., F.R.C.S. (Eng.) and Philip Turner, B.Sc., M.S., F.R.C.S. (Eng.). Two Volumes. Seventh Edition. London: J. & A. Churchill, 1927. Pp. 1940, with 900 illustrations (43 in colour). Price, £3-10-0.

It is twelve years since the sixth edition of Jacobson's famous book was issued and one had begun to fear that it was doomed to extinction, along with Erichsen, Bryant and other great books of the past. In surgery, as in other branches of science, it becomes increasingly difficult to keep an old book abreast of advancing knowledge without rewriting it to such an extent that it has almost totally lost its original character. The disappearance of Jacobson's name from the title would seem to indicate that the present authors, who in the preparation of the sixth edition practically re-wrote the volume on abdominal surgery, feel that this stage has now been reached. Still those who can recall the late Mr. Jacobson's gifts as a teacher, his profound erudition, his quaint personality and his homorously sarcastic manner will regret that his memory was not perpetuated for at least one edition after his death.

There are many good books on operative surgery written for the student, concise and dogmatic; there are others intended for practitioners, equally dogmatic but not so concise, which give excellent accounts of the exact technique considered best in his particular branch by each one of a group of specialist writers, none of whom waste much space in discussing other methods than those which their experience has led them to adopt. Jacobson's book differed from these in the breadth of its outlook, in the philosophical discussion of pros and cons, and in the author's profound knowledge of the literature of the subject which was reflected in his writings.

The work of revision has been done with great care and the authors have preserved the original character of the book as far as possible while bringing it up to date. Room has been made for new matter by cutting down old case reports, discarding old methods, shortening many of the discussions on indications for operations now falling out of use, and by the free use of small type. We miss the numerous references to "my old friend Mr....." and "my late colleague Dr....." which gave such a human touch to famous editions. Many footnotes which were added in the last edition still appear as footnotes, though they often deal with

such important points that their proper place is in the text. The result of this process of compression is that the book is practically unchanged in length, though much new matter and many additional illustrations have been added. All the old sections on ligations of arteries with their beautiful coloured illustrations are preserved for the benefit of examiners, but it is to be regretted that the new anatomical nomenclature is not given as well as the old.

It is impossible to do more than indicate briefly the principal changes which have been made. The advances in surgery made during the war have all been incorporated, and we find excellent new sections on shock, regional anæsthesia, blood transfusion and guillotine amputations. The chapters on head injuries, wounds of great vessels and wounds of the chest and abdomen have been entirely re-written, borrowing freely from the official history of the war. Mr. Trethowad is mainly responsible for the orthopædic operations and though we find excellent accounts of bone grafting and of the surgery of spastic and infantile paralysis, those of arthroplasty are too short to be of any value. The chapters on cranial surgery have been re-written and the writings of Tooth and Cushny are freely quoted, the technique of alcohol injections of the branches of the fifth nerve and the modern operation on the Gasserian ganglion by neurectomy of its sensory root are included. The articles on the tongue and on the thyroid follow the old lines too closely, there is no mention of the use of diathermy in excision of the tongue, nor of the wedge resection method of partial thyroidectomy nor of the method of safeguarding the recurrent laryngeal nerve by leaving a slice of thyroid tissue *in situ*. The chapters on plastic surgery of the face have been entirely re-written, incorporating Gillies' work and also his highly original operation for cleft palate. A much fuller discussion of the present position of operative treatment of tuberculous glands of the neck and some anatomical illustrations would be a welcome addition. The modern views on the spread of breast cancer are well described, but the method of operation advocated—by dealing with breast first and finishing with the axilla—is not that adopted by most surgeons. Recent work on the surgery of pulmonary tuberculosis, the thoracoscope and division of the phrenic nerve are fully dealt with. The changes which surgery has undergone are sharply brought out by a comparison of the chapters on operations on the lower extremity in the present edition with those in the former. The long discussion on the control of hæmorrhage in amputation at the hip joint has disappeared, the 10 pages which were devoted to excision of the hip have come down to 2, Carden's, Gritti's and Stokes' amputations have been scrapped, along with tarsectomy, excision of the knee joint and all except one method of excision of the ankle joint. Periarterial sympathectomy and some of Hey Groves' reconstruction methods are included and of course Albee's and Hibb's operations for fixation of the spine.

In Volume II which deals almost entirely with abdominal surgery we find fewer changes. In the sections on hernia there is a lot of new matter, including a detailed description of Mr. Turner's own operation, but it is surprising to find no mention of the work of Gallic and Lemesurier. The authors are conservative in their operative treatment of gastric ulcer, they advise excision combined with in most cases rather than aseptic method of together with Fraser and Dotts application of it to excision of growths of the colon. All reference to Murphy's button is omitted—another milestone marking the change of methods. Long and excellent sections on diaphragmatic hernia, on diverticulitis and on reconstruction operations on the bile ducts and the ruthless cutting down of the chapter in which Lanes' views on intestinal stasis were expounded indicate the changing views of surgeons. Thomson Walkin's operation for enlarged prostate is described and also Young's method of perineal prostatectomy with many of the original illustrations, but the preliminary investigations on which the decision to operate in two

stages is made might be given on more detail. The chapter on malignant disease of the rectum has been brought up-to-date and Kraske's operation has been dropped out, as it has in the practice of most surgeons.

It will be seen that, with the exception of a few points criticised, the book has been brought well up-to-date. It has always been a favourite with serious students and with candidates for the final F.R.C.S. examination. We consider that the present maintains the traditions of the former editions and that the book will maintain its former popularity.

W. L. H.

EMERGENCIES OF A GENERAL PRACTICE.—By N. C. Morse, A.B., M.D., F.A.C.S. Revised and Re-written by A. W. Colcord, M.D. Second Edition. St. Louis: The C. V. Mosby Co., 1927. Pp. 541. With 311 illustrations. Price, \$10.00.

THIS book gives in comprehensive yet succinct form an account of those emergencies which arise in the course of every general practice: it will be welcomed by the practising physician who would otherwise have to seek out his information from numerous works on surgery, laryngology, ophthalmology, obstetrics, etc.

After a preliminary chapter in which are set forth useful lists of emergency instruments, solutions and ointments in common use, Dr. Colcord passes to a consideration of the removal of foreign bodies from the ear, eye, throat, rectum, etc. He sounds a note of warning on the possible results of ill-timed efforts at removal, and urges that the aid of a specialist be invoked in all cases except those of great emergency where every minute is of value. There is a well merited appreciation of the work of Chevalier Jackson on the use of the laryngoscope, bronchoscope and esophagoscope.

Chapter III is devoted to first-aid: in the treatment of shock, the importance of getting the patient away from gaping crowds, keeping off hysterical relatives and refraining from fussing is perhaps too little appreciated. The following chapter deals with asphyxiation from drowning, smoke, gas and electric shock: the section on carbon monoxide poisoning is particularly well done and the necessity for immediate rest even in mild cases of poisoning by this gas, in order to conserve the oxygen supplies of the body is strongly urged. The subjects of shock, wounds and bruises are then considered: in connection with the first of these it is pointed out that the use of heart stimulants in exhaustion shock is futile and may be actually harmful. The account of the general treatment of a wound (say of the forearm) in the surgery is excellent: reference is made to the Carrel-Dakin method of wound sterilization and to the work of Kanavel on infections of the hand. The section on bruises and sprains is fuller than is commonly found in text-books of surgery.

The treatment of various emergencies of a surgical or medical nature, including ptomaine poisoning, is next taken up; then follows a section on burns with an account of the modern paraffin method of treating this form of injury. The remainder of the book, with the exception of a brief but very welcome chapter on extraction of teeth, is mainly devoted to the subjects of fractures, dislocations, amputations, obstetric emergencies, and poisoning. The value of inspection in the diagnosis of fractures is pointed out, and the danger and unnecessary pain associated with misguided attempts at eliciting crepitus are emphasised.

The use of water "and plenty of it" in the immediate treatment of burns by strong mineral acids is recommended: the application of alkalis in such cases merely induces a brisk chemical action which probably increases the existing tissue damage.

There is little to criticise in this excellent volume. We had not hitherto imagined, however, that Tacitus lived as early as 450 B. C. (p. 78): *without* (at the bottom of page 89) is an error in printing, but surely 70 to 20 per cent. (p. 90) is wrong. Perhaps rather a fuller account of the sites at which spouting arteries

may be most usefully compressed might have been given. In the description attached to Fig. 95 (p. 181) "Is applying" should read "In applying." In connection with the reduction of hernia mention might have been made of the fact that pulling down the mass immediately prior to its attempted return to the abdomen not infrequently relieves the swelling at the neck of the sac and enables the subsequent manipulations to be carried out with greater possibility of success. On page 332 "spinal" should be "spiral": if Fig. 182 represents a fracture of the *right* clavicle as stated, it seems rather unusual that the following four figures should show the same subject being treated for a fracture of the left collar bone. Fracture of the metacarpal "of" the proximal phalanx (p. 371) is again a printing error, but surely Dupuytren's splint is not applied in Pott's fracture in order to cause *eversion* of the foot (p. 395). The symptoms and diagnosis of fractures of the base of the skull are rather briefly dealt with and the composition of Schleich's solution (p. 217) might usefully have been included. These minor blemishes do not detract from the general excellence of the work: it is a book that no general practitioner should be without.

J. M. H.

A STUDY IN TUBERCLE VIRUS, POLYMORPHISM, AND THE TREATMENT OF TUBERCULOSIS WITH OLEUM ALLII.—By William C. Minchin, M.D. (Dub.). Third Edition. London: Baillière, Tindall and Cox, 1927. Pp. xvi plus 110. With 26 plates and 1 text figure. Price, 25s. net.

THIS book is divided into two parts: Part I is a study of tubercle virus, while Part II deals with the treatment of tuberculosis with oleum allii, or oil of garlic. Researches extending over a number of years have forced the author to the conclusion that tuberculosis is not entirely explained by Koch's bacillus. He supports his contention by reference to the well-known fact that microscopic examination of pus from clinically tuberculous joints and glands, of exudates in cases of pleural or peritoneal tuberculosis or of meningitis frequently fails to detect the presence of the abovementioned organism.

Tubercle bacilli often contain spheroidal bodies and to these the author attributes the disease: the bodies in question have been noted by different workers and have received different names. The author of this volume refers to them variously as "spheres," "yeasts" and "granules": some of them at least are identical with the granules described by Much and called after his name. Two different varieties are distinguished, a larger type staining deep black-violet with Ziehl-Neelsen's stain and a smaller staining red by this method. The former can undergo extensive metamorphosis and some at least are converted into bacilli. The "granules" or "spheres" are filter-passers; filtrates of tuberculous pus containing them but free from bacillary forms have given rise to typical generalised tuberculosis in guinea-pigs with numerous bacilli scattered through the body. Such bacilli have arisen from the "spheres" or "granules": in active disease bacilli are seldom found but active budding of the "spheres" is always present.

The author's arguments may, in his own words, be summarised thus:—"Now the T. B. virus exists as a rod, stretching and dividing: as a yeast sphere elongating into a bacillus; and as a yeast sphere reproducing by the process of budding."

In view of the above, the ideal drug for the treatment of tuberculosis should be one which is rapidly absorbed and which is capable of destroying the "spheres": such a drug is oil of garlic, the beneficent properties of which are due to the allyl groups which it contains. Very remarkable results have been obtained by the author in cases of pulmonary and laryngeal tuberculosis, bone and joint tuberculosis and in lupus. He insists on the fact that results can only be achieved when the oil can get at the "spheres." In shut-away cavities where those offenders are protected by fluid,

improvement cannot be hoped for until the focus has been thoroughly opened up by surgical measures. Oil of garlic can be used in various ways—by external application as a poultice, by internal administration, and by inhalation: the last method largely overcomes the objectionable odour that appears in the breath when the drug is orally administered.

We have little to criticise in this book: the views put forward are certainly worthy of further study. The author states (page 43) that he has obtained good results from "Yadil." This preparation and the makers thereof were exposed some two years ago by a leading English newspaper. It was conclusively shown at the time that the chemical composition of "Yadil" was apparently not the same as that claimed by the manufacturers. Leading pharmacologists also gave it as their considered opinion that its pharmacological and therapeutic actions were probably nil.

The photographs and micro-photographs, the printing and the general get up of this volume are alike good.

J. M. H.

MINOR SURGERY.—By A. E. Hertzler, M.D., F.A.C.S. and Victor E. Chosky, A.B., M.D., F.A.C.S. St. Louis: The C. V. Mosby Co., 1927. Pp. 568. With 438 illustrations. Price, \$10.00.

In this admirable little book the authors have succeeded in placing before students a clear picture of the various conditions they may be expected to see daily in any surgical out-patient department. Its title, *Minor Surgery*, describes it accurately, for in no place in the book is anything in the nature of major surgery touched upon, with the possible exception of the radical cure of inguinal hernia. Each region of the body is dealt with in turn and all the common accidents and ailments which are likely to happen to it, and their treatment are described in an excellent manner. A prominent feature is the wealth of good photographs and diagrams with which the book is endowed, and which greatly help the student to understand the text and recognise conditions. We consider this *Minor Surgery* to be one of the best of the smaller works on surgery, and recommend that it should be read by all young medical men and women who are about to take up an appointment of house surgeon.

THE HEART.—By Alexander G. Gibson, D.M., F.R.C.P. (Lond.). Bombay: Oxford University Press and Constable and Co., 1926. Pp. 108. Price, 5s. net.

THIS is one of a new series of Oxford Medical Handbooks, designed to deal shortly with the fundamental principles which underlie their subjects and to illustrate these by their application in general practice. Its appeal is therefore primarily to the general practitioner. The question of what to include and what to omit must always be a matter of opinion in a synopsis and the author craves indulgence on this question. On the whole he has succeeded in compressing into small space most of the essential facts about the heart and its diseases. If we have any criticism to make it is that more space might have been given to the medicinal treatment and the modern work on the standardisation and use of digitalis, and on the indications for quinidine. No bibliography for general practitioners should omit *The Beloved Physician*, for he will find in the description of Mackenzie's investigations, the solution to just those cardiac problems that text-books rarely seem to solve.

OBESITY.—By Leonard Williams, M.D. Bombay: Oxford University Press and Constable and Co., 1926. Pp. x plus 171. Price, 10s. 6d. net.

DR. WILLIAMS is best known as the author of *Minor Maladies*, an invaluable work to all general practitioners. In this volume on obesity we have a sound readable monograph on the subject, written in a style peculiarly the author's own. Dr. Williams has succeeded in producing a volume suited to both the lay and the professional reader, scientific and logical in its

argument, and yet as easily read as the most recent "best seller." When we add that the word "calorie" does not occur once in its 166 pages, and that he believes that "physical exercise in woman, unless it be exhaustingly vigorous and long sustained, leads to an increased deposit of adipose tissue" we have said enough to indicate that it is a book those called on to treat obesity must read.

HEWAT'S EXAMINATION OF THE URINE AND OTHER CLINICAL SIDE-ROOM METHODS.—Revised by G. L. Malcolm-Smith, M.B., Ch.B., F.R.C.P. (Edin.). Seventh Edition. Edinburgh: E. & S. Livingstone, 1926. Pp. 228. Price, 3s. net.

DR. HEWAT'S handbook on the examination of urine and other clinical methods has always been a popular and useful book. Dr. Malcolm-Smith in bringing out the seventh edition of the book has taken care to maintain the main portion of the work, and has at the same time, thoroughly revised the text and added some of the modern techniques briefly. The book does not contain any elaborate methods of analysis but is suitable for those whose laboratory experience is limited. It should help students in learning some of the recent methods of laboratory analysis which are described simply in the book.

The main portion of this book deals with examination of the urine. The author has gone through the whole subject in a commendable manner. The book contains a lot of illustrations. A few new sections have been added to this edition, such as fractional gastric analysis, renal efficiency test, and examination of the cerebro-spinal fluid.

In the section of "the feces," the author has given short notes on the macroscopic, chemical and microscopical examination; but no mention has been made regarding intestinal parasites. A short illustrative section on some of the common intestinal parasites, worms and protozoa would not at all have been out of place and in our opinion would have enhanced the value of the book.

The book is of a convenient size and can be easily carried in the pocket. We recommend it as an useful book for ready reference.

J. P. B.

A PRIMER FOR DIABETIC PATIENTS.—By Russel M. Wilder, M.D. Third Edition. London and Philadelphia: W. B. Saunders Company, Limited, 1927. Pp. 134. Illustrated. Price, 7s. 6d. net.

IF, in any disease, the faithful and intelligent co-operation between the patient and his doctor is needed most, it is in diabetes, and the author must be congratulated on bringing out a primer for the use of such patients. With the help of this book, it is hoped, they will be able to understand the rationale of the treatment, without which successful treatment of diabetes is almost impossible.

It may be argued that a little knowledge is dangerous. It often is, it is true; but the idea of the author in writing this book seems to be quite different. He has not intended the book to be used as a sort of "Family Physician" for self-treatment. In a disease like diabetes, if the patient takes up treatment in his own hand without any medical advice the result may be disastrous.

The book contains a lot of useful information:—food scales; caloric value and composition of foods; how to determine the tolerance; diet; prescriptions; insulin and its use; complications and their treatment, etc.; dealt with in simple language which may also help the busy general practitioner, who usually has no time to go through bigger and more elaborate treatises on the subject.

We have no hesitation in recommending the book to those for whom it is intended and also to the busy general practitioner for ready reference.

J. P. B.

Annual Reports.

ANNUAL REPORT OF THE KING EDWARD VII SANATORIUM, BHOWALI, U. P. FOR 1926. BY CAPTAIN R. K. KACKER, I.M.S. (PUNJAB), T.D.D. (WALES), LATE I.M.S., MEDICAL SUPERINTENDENT.

We are glad to receive this report, for it shows what excellent work is being done at Bhowali under the able direction of Captain Kacker. The Sanatorium is run by a trust committee, consisting of official and nominated members, and of non-official members elected by the U. P. Legislative Council. Its income is derived partly from government grants, but in almost equal measure from fees from patients, subscriptions and donations, and interest on capital. Remarks made by the I. G. C. H. and by Colonel Sprawson, I.M.S., in the visitors' book during the year show how much the work of the Sanatorium is appreciated in the Provinces. The report is illustrated with beautiful photographs, showing the beautiful mountain setting of the Sanatorium, the very attractive type of open air cottages provided, and the character of the buildings.

The accommodation at the Sanatorium is at present 74 beds, but it is hoped to raise it to 84 during the current year. A need which has been felt for a long time was the construction of a separate administrative block; thanks to a government grant the construction of the building has now been started. A point which will interest other medical superintendents in India is that the Sanatorium Committee has decided that all building work shall be carried out, not under the P. W. D., but by direct contract with the contractors, under the supervision of Mr. J. D. Grant, A.M.I.E., who has been appointed Consulting Engineer to the Sanatorium. The Superintendent reports that, although this involves extra work for him, "the system certainly makes for economy, expedition, and smooth working."

During the year a special grant was made for an x-ray apparatus, the need for which was very urgent, especially in connection with artificial pneumothorax treatment. In the first place, a small portable apparatus is being purchased; but later, if an electric supply can be obtained from the Naini Tal hydro-electric supply, a larger plant will be installed. A second step forward has been the appointment of a well qualified Assistant Superintendent, Y. G. Shrikhande, M.B., B.S. (Lucknow), B.Sc. (Allahabad), who is well qualified in laboratory and bacteriological work, and who—it is interesting to note—is himself an ex-patient of the Sanatorium. During the year three medical men applied for permission to work as honorary workers at the Sanatorium in order to "acquire merit," and permission was granted. It is intended in the future to organise regular classes for the special training of medical men who are either deputed by government or anxious as volunteers to learn modern methods of diagnosis and treatment. Of the urgent needs of the Sanatorium Captain Kacker writes very strongly; the first necessity is to raise the accommodation to beds for 100 patients, since at present two patients are turned away for every one admitted; the second urgent need is the provision of a nursing block for such patients as are seriously ill, require nursing, and who cannot be properly looked after in the cottages; the third urgent need is for the supply of electric current.

Turning to the more specific report for the year, no less than 490 persons applied for admission during the year, of whom only 275 furnished the full information required by the prescribed forms; and the Superintendent draws special attention to the rules for admission which are clearly set out in an appendix to the report. There are certain classes of patients who should not be sent to such a sanatorium in the hills; the destitute; acute febrile cases; patients with cardiac or renal complications, and others. In this matter there rests a real responsibility on the medical profession in India, for the accommodation is so severely limited that only suitable patients

can be admitted if the best use is made of the Sanatorium. In all 136 patients were admitted for treatment during the year, and more than 36 per cent. of them came from outside the United Provinces. In the table of occupations the special incidence of pulmonary tuberculosis among clerks and students is noteworthy; also the table of age incidence, which shows that in India the chief stress of the disease falls upon adults of from 20 to 40 years of life. No less than 51 per cent. of patients admitted were cases in stage III, and these advanced cases are in reality unsuitable for sanatorium treatment.

The average period of stay in the Sanatorium works out at 118 days, and considering that 92 per cent. of patients showed tubercle bacilli present in the sputum on admission, this must be considered a very satisfactory figure. The regime prescribed in the Sanatorium is the usual one of rest—both physical and mental—and graduated exercises, and Captain Kacker reports that he hopes to supplement the latter by occupational therapy, as patients who are on the road to recovery are apt to find time hang heavy on their hands. Where such measures do not induce a satisfactory response, recourse is had to special measures.

Of these, antiseptic inhalations are of appreciable value. Tuberculin, B. E. has been used on a certain number of cases, but has produced no striking results. Sodium morrhuate has been completely disappointing. Sano-crysin has been tried on four cases, but this line of treatment had to be abandoned in three of them owing to febrile reactions; in the fourth case it seemed to be of value.

Artificial pneumothorax was tried in 26 cases, although this line of treatment was particularly handicapped by the want of x-ray apparatus. In 14 of these cases the results were very good, whilst the only complications observed were a tendency to faintness owing to pleural shock in one patient, and febrile reactions in 4 cases—possibly owing to impurity in the novocaine solution employed. The laboratory work increased greatly during the year, owing to the appointment of a fully qualified Assistant Superintendent, and routine examinations of urine and faeces were made in all patients, and the albumin reaction of the sputum tested in doubtful cases. The blood sedimentation test is under trial.

The total income for the year was Rs. 88,851—including a special donation Rs. 15,000 from Mr. C. F. Sassoon,—and the expenditure Rs. 52,851; leaving a balance of Rs. 36,000.

The annual reports of the Madanappelle and of the Bhowali Sanatoria show that a beginning at least has been made of tackling the terrible problem of pulmonary tuberculosis in India. As Dr. Fridtjof Möller has pointed out in our columns, the policy of tuberculosis dispensaries in the large cities of India will lead nowhere unless there are available sanatoria to which selected patients can be sent. The tuberculosis dispensary should serve as a clearing station for cases, selecting those suitable for sanatorium treatment, and rejecting others. Pulmonary tuberculosis in India, perhaps the third or fourth of the seven scourges of India, can only be controlled by proper methods of town planning and rebuilding; and it is a problem of Indian cities and not of the Indian countryside.

Captain Kacker is to be congratulated on a most interesting report of a most valuable year's work.

REPORT OF THE HEALTH OFFICER OF CALCUTTA FOR 1925. BY DR. T. N. MAJUMDAR, D.P.H., D.T.M., F.C.S. (LOND.), F.R.S. (EDIN.), CALCUTTA: PRINTED AT THE CORPORATION PRESS. 1927.

CITIES are an expression of the herd instinct in man, and in the congregations of men there is opportunity for much evil and much good. Up to the time of Chadwick and Sir John Simon most cities had been dens of filth and disease. "Carpe diem" was the

motto of most city dwellers, for life was very uncertain. It was these two pioneers of common sense sanitation who showed that by intelligent application of the knowledge of the causation of disease, by a pooling of common resources and wealth, conditions in cities could be made much better and safer than in the country. The continued application of these principles has resulted in an immense improvement in the cities of England. London for instance has one of the lowest death rates of the Empire, and speaking generally the sanitary conditions of the English towns are far better than in the rural districts.

Over 80 per cent. of India's population still lives in villages and small communities, but there is evidence that urbanization is increasing. The health and sanitary conditions of India's large cities are therefore matters on which the attention of the whole country is focussed, being as they are an index of sanitary progress. Sanitation should be able to achieve in the cities of India the improvement which has been shown to be possible elsewhere.

The health of Calcutta, India's largest city, is thus a matter of national importance. Can we discern in its yearly reports any evidence of that improvement which the optimists and well wishers of India hope will soon begin to spread over the land?

At first sight there is a feeling of disappointment. Out of a population of 1,077,264, there were in 1925, 35,195 deaths, giving a death rate of 32.7 per mille.

The birth rate was 18.9. 3,923 lives were lost from small-pox, a death rate of 3.6 per 1,000; nearly 1,000 people died of cholera, and 1,586 from tuberculosis, a death rate of 2.4 per 1,000.

The infant mortality rate was 326 per 1,000 births. These figures are not cheering. It would take more space than is available to attempt to scrutinise all the causes and factors that hinder Calcutta's sanitary progress. Climate no doubt is a big factor; centuries of comparative poverty and yearly visitations of tropical epidemics have engendered in the population a feeling of callousness towards life and death, and "Karma" is at once a consolation and an opiate. The wish for life is not strong enough to put into practice the knowledge that in these days should be obtainable.

Dr. Majumdar gives a very interesting curve of the total mortality for 20 years. From 1906 to 1917 the death rate fell steadily from 37 to 23.5. Then came the disastrous influenza epidemic from which the city recovered in 1923. Since the latter date, however, the death rate has shown a disquieting steady rise for which there seems no adequate reason save increase of disease.

Dr. Majumdar also gives a very interesting analysis of the city's health. The "added areas" have increased Calcutta's responsibilities, but have not added to its health. These areas are more malarious, and have a higher death rate than the old Calcutta. A very instructive map on page 3 shows the death rate by wards; Buntally has a death rate of 66.4 and Watgunge 62.6, Beniapukur and Satpukur 46.8 and 46.3 respectively; pretty high figures these! The causes given are child mortality, poverty, poor housing, deficient drainage, defective water-supply and ill cared for service privies. Can the city afford to improve the conditions in these bustee areas? Would the return in health be commensurate with the expense? Would the benefits be lasting? There is a table on pages 3 and 4 which gives one to think, a table of the causes of death in Calcutta in 1925.

Small-pox easily heads the list, then come respiratory diseases, then tuberculosis and, high on the list comes (unexpectedly), old age! Perhaps soon one of our Calcutta Ciceros may write a "De Senectute Calcuttiense." Next comes, as if in mockery, premature birth and congenital debility, then malaria and dysentery. Tetanus kills 1,161 people in Calcutta in the year, more than diarrhoea and enteritis.

Bernard Shaw in "Back to Methuselah" says that the average man is a coward and doesn't wish to live

beyond 70. There is a great deal in this. The desire to live long and to make the most of that life is not strong enough in India. Life is too cheap to be taken so much care of. Until we get a change in this point of view, public health measures are going to avail little. The high infantile mortality, 326 per 1,000 is but another expression of the cheapness at which life is valued by the population in general. Syphilis is stated to be the cause of a large proportion of premature births, and tetanus kills more than a half of those babies who die between a week and a month old. The Corporation Health Department does excellent work amongst poor women and children, though it is too early yet to measure benefits by figures.

There are twice as many males as females in Calcutta, which results in a comparatively low birth rate. It is distressing to read that there are 20,000 prostitutes in Calcutta.

Cholera in 1925 accounted for 0.92 per 1,000 deaths. From the mortality graph however it is hoped that cholera is on the downgrade. The recent propaganda work in inoculation should help towards a farther reduction, if pushed consistently and constantly. Cholera is mainly a disease of Hindus in Calcutta, and confined to the riparian and water-logged wards. Small-pox appeared in epidemic form; out of 3,304 deaths 435 occurred amongst children under 1 year and 899 in children from 1 to 5. Primary vaccination is therefore much neglected. The Vaccination Act of Bengal is too cumbrous in application and needs revision.

Malaria, if figures be true, killed more persons in Calcutta in 1925 than cholera, the death rate being 1.6 per 1,000.

Anopheles stephensi form about 1 per cent. of the anopheles in the malarious districts. Mahomedans suffer four times as much as Hindus from malaria in Calcutta.

Diarrhoeal diseases are common and where conditions of sewerage, water-supply and latrines are defective should be capable of immediate reduction by improving these.

Tuberculosis kills 2.4 of every 1,000 yearly and would appear to be on the increase. The returns are practically all *Phthisis*. The age and sex incidence is pitiable, the death rate in females between 15 and 30 is 6.5 per 1,000, a terrible condition of affairs. Dr. Majumdar cites early marriage as the most important factor.

Respiratory diseases are a large factor in Calcutta, mortality due to them accounting for 6.5 per 1,000.

Kala-azar is apparently increasing, even when allowances are made for the large numbers of cases that come for treatment from outside.

In section III Dr. Majumdar gives an excellent account of the activities of his department. Abatement of nuisances and the improvement of insanitary buildings form the bedrock of environmental improvement: 6,099 notices were issued as compared with 5,601 in 1924. The improvement of insanitary areas is closely linked up with the work of the Calcutta Improvement Trust which has demolished many such areas, but as Dr. Majumdar points out new construction has not been commensurate with demolition, and this very important factor in the prevention of slum areas must be very carefully watched both by the Corporation and the Trust. The Trust scheme for the Anglo-Indian classes and for the poorer classes in Ward Institution Street have been successful, but a scheme to the North for middle class Indians has not proved successful.

Food inspection and the prevention of adulteration are very important duties of the Health Staff. Under the 1923 Act a special sub-committee reported on the standards of purity of certain foodstuffs to be prescribed under the Act. The milk supply is a very difficult problem and no less an important one, as under modern conditions of life the growth factors necessary for infant, child and adolescent growth are difficult

to obtain from any other source. It is not surprising then that the Corporation should encourage the development of a better milk supply. While larger schemes are under consideration the Corporation meanwhile subsidises the Co-operative Milk Society's Union which guarantees to produce 500 out of the 4,000 maunds of milk daily used in Calcutta.

The Corporation undertakes a considerable amount of medical relief, and endeavours to pay special attention to malaria, kala-azar, and phthisis. A pleasing feature is the increasing use being made of maternity homes and child welfare centres. 4,748 maternity cases were attended by Corporation midwives, i.e., 2 per cent. of the total registered births of Calcutta. Only 13 maternal deaths occurred in these, a very much smaller proportion than happens without such aid. The Corporation Laboratory shows an excellent record of work during the year. Dr. Majumdar discusses the necessity of chlorination of the filtered water-supply at its source. There is no doubt that the quality of the filtered water deteriorates during the rainy season and Dr. Majumdar considers that chlorination during that period would be an additional safeguard.

Dr. Majumdar in his interesting report shows that he has a clear conception of the sanitary conditions of Calcutta and of the city's necessities. Sanitary progress, however, depends on many other factors than a health staff. We wish Dr. Majumdar and his staff every success in their strenuous efforts.

A. D. S.

ANNUAL ADMINISTRATION REPORT OF THE ASANSOL MINES BOARD OF HEALTH, FOR THE YEAR 1925-26.

THE Asansol Mines Board of Health is one of the few "ad hoc" sanitary authorities in India and its reports are of considerable importance in demonstrating what can be done by an authority furnished with the necessary legal powers and with adequate funds and a well organised staff, in combating infectious and epidemic disease and in improving environmental conditions generally. In appendix F, is given a comparison of death rates and birth rates, etc., between Asansol Mining Settlement and the cities of Calcutta, Howrah, and Dacca. The death rate of the Settlement was 16.11 as compared with 33.43 for Calcutta, the birth rates being 28.87 and 17.32 respectively. The purpose of the comparison is not quite apparent, as the age and sex compositions of the Settlement and these towns are quite different, and the vital statistics not therefore comparable without considerable adjustment. A better comparison would be with some of the surrounding parts of Asansol sub-division not in the Settlement, or adjacent parts of Burdwan or Bihar.

On page 9 is an instructive table showing how since 1920 the deaths in the settlement have decreased from 8,597 to 5,544 in 1926 and the births increased from 8,669 to 9,945, the "natural increase" having gone up from 72 to 4,401. Cholera and small-pox are the *bête noirs* of this area and much of the organisation is directed towards the prevention and spread of these diseases. In the spring of 1926 a serious small-pox epidemic threatened which was held in check by wholesale vaccination and revaccination. 1,129 cases occurred, 336 in unprotected persons with a mortality of 15.5 per cent., compared with a mortality of 9.3 per cent. in cases previously protected. 415 cases of cholera occurred with 206 deaths, giving a death rate of 0.63 per 1,000 and a mortality rate of 50 per cent.

Important research work carried out by Dr. Tomb and Captain Maitra, I.M.S., has been reported in the *Indian Journal of Medical Research* and *The Indian Medical Gazette*. Malaria and plague were negligible as causes of mortality. The infantile mortality rate was 120 per 1,000 registered births, and compares favourably with anywhere in India. The water-supply has been improved by twelve additional wells. A feature of the Board's work has been the education

of school children in health matters and the medical inspection of school children.

The organisation of the Board is thorough and complete and the chief sanitary officer is to be congratulated on another year's excellent sanitary progress.

A. D. S.

HEALTH DEPARTMENT. CIVIL AND MILITARY STATION, BANGALORE. ADMINISTRATION REPORT FOR 1925-26. BY S. AMRITARAJ, HEALTH OFFICER, BANGALORE.

THE civil station of the Bangalore has an all-time Health Officer, Dr. Amritaraj, who submits an interesting report on the year's sanitary happenings. There are nearly 120,000 inhabitants in the civil station, the majority being Hindus.

The birth rate was 39 and the death rate 30 per mille, the infantile mortality rate being 214. These are lower rates than the previous year, especially noticeable being the fall in the infantile mortality rate from 273 to 214. Child Welfare and Maternity Work is taken up vigorously and Dr. Agnes Scott in an inspection note made very complimentary remarks. Lung diseases show by far the highest mortality, bowel complaints coming next. Other diseases such as malaria, enteric, small-pox, etc., contributed only in a small measure to the total mortality. There were no cases of indigenous plague. 19,000 rats were destroyed, some of which were plague infected. Inoculations were carried out in the areas indicating the presence of rat plague.

Careful inspection and control are maintained over *dhobi* ghats, private and public markets, and slaughter-houses. The filtered water-supply is scanty and many wells had to be reopened. Careful and systematic disinfection of these was successful in preventing completely any outbreak of water-borne disease.

The report bears evidence of careful, systematic and consistent good work and we wish Dr. Amritaraj and his staff success in their efforts.

A. D. S.

ANNUAL REPORT OF THE EXECUTIVE HEALTH OFFICER OF THE CITY OF BOMBAY FOR 1926. BOMBAY TIMES PRESS.

COMMON sense and experience are the best interpreters of vital statistics. They are necessary, for at first glance we might draw very adverse conclusions from the figures of Bombay; its death rate in 1926 was 25, its birth rate 16.47 per mille, and the infantile mortality rate 390 out of every 1000 children born. We might be apt to say that at this rate Bombay would shortly cease to have any inhabitants at all. But the Health Officer explains that a great proportion of the women of Bombay go to their homes for their confinements and in a few weeks come back with the newly born children to Bombay. These births are not registered in Bombay, but the infant deaths are. The birth rate and the infantile mortality rate do not therefore represent the real state of affairs. Cholera was negligible in 1926, only 5 deaths occurring; small-pox accounted for 480 deaths, 0.37 per mille; and tuberculosis for 1,755 deaths or 1.37 per mille.

It is to the large cities in India that we should look for a lead in sanitary matters. The Bombay report contains matters of considerable interest, but does not particularly arouse optimism that Bombay is on the way to the realisation of great sanitary hopes. The infantile mortality rate, corrected for registrations outside Bombay, still has a figure of 255. Malaria is probably the added factor giving this high mortality. Captain Chalam, I. M. S. reports that out of 36 children under 2 living in railway quarters, one in every 3 had an enlarged spleen, and one in every 6 showed malarial

parasites in the blood. Much is being done by municipal nurses, midwives, maternity homes, milk depôts, etc., to correct the high infant death rates.

Plague is still endemic to Bombay, and 0.45 per cent. of rats examined (283,050) were infected.

Bombay has three anti-tuberculosis institutions, which appear to do good work.

Malaria is always a danger in Bombay and if things were left to themselves would soon be a very serious menace. The Back Bay Reclamation scheme was recognised to be dangerous and a special officer was deputed for anti-malarial work. Dr. Sandilands is of opinion that malaria is widely prevalent in the city.

Bombay consumes 3.1 ounces of milk per head per day. We are surprised to find that 78 per cent. of milk comes from milk stables in Bombay city. We had an idea that these stables had been abolished, and that up to date arrangements have been made to bring milk by cold storage trains from outside.

The water supply is still unfiltered, but the greater part is chlorinated throughout the year.

The interesting question of the sewage disposal is not discussed. It is of course more an engineering problem. The scheme for remodelling the whole system is still under consideration. One notes that the old "basket privies" are still damned and still exist.

The housing problem of Bombay is a big one. 35,000 houses are inspected yearly by the health staff. Tenements or chawls are the favourite class of inferior house; of the total tenement population 66 per cent. live in one-roomed houses, and 56 per cent. of the total births in the city occur in these one-roomed families. No wonder the women wish to retire to the comparative quiet and privacy of their country homes to have their children.

The report is an interesting one and gives a record of much laborious work done by Dr. Sandilands and his staff.

Correspondence.

PERSISTENT HICCUGH ASSOCIATED WITH ASCARIS INFECTION.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR.—About five months ago, when I was in charge of the Local Fund Dispensary, Shirdahalia, I was called in to see a Hindu male patient, aged about 35 years, who had been suffering from persistent and most obstinate hiccough for a week. The attacks were so continuous and so severe that the patient felt himself half suffocated. Vomiting was also present, and the patient could retain no food. The patient informed me that seven or eight years previously he had had a similar attack, which lasted for ten days or so.

Physical examination of the patient showed no obvious cause for the condition, and he was a generally healthy individual, whilst the complaint had set in suddenly without previous warning or ill-health. I particularly enquired whether he had ever suffered from round-worm infection, but this he emphatically denied.

The usual lines of treatment, such as effervescent mixtures, blisters to the epigastrium, sedative drugs—such as bromides, chloral, and opium—were all tried, but failed to give any relief. Gastric lavage could not be attempted owing to the severity of the symptoms and the patient's sense of partial suffocation. Morphine was administered hypodermically at nights, but gave only partial relief; as soon as the patient woke up the condition recurred. It persisted for a fortnight, by which time the patient was bed-ridden, and owing to his inability to retain food, in a condition of great prostration.

As a last resort, I administered santonin and calomel, three repeated doses. The next day the patient

had two stools in which he passed about 20 full grown round-worms. The hiccough now gradually lessened and by the subsequent evening had completely ceased. Next morning he was given a mild purgative, when he again passed a further half dozen round-worms, numbering about two dozen in all. The symptoms immediately ceased and the patient is today in excellent health.—Yours, etc.,

K. M. HULI RAO, I.M. & S.
Assistant Surgeon.

ARTHRITIS AS A COMPLICATION OF SMALL-POX.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR.—With reference to Dr. Gopal Singh Chawal's letter in your issue for May, 1927, may I be permitted to say that septic arthritis is not an uncommon complication of small-pox? At the present moment I have under treatment a patient, a boy five years of age, who suffered from small-pox a month ago. As a result, he now has septic arthritis of both shoulders, knees and elbows. His shoulder joints are enormously swollen and discharging pus. I last saw him on the 11th August, when the suppuration had ceased, but had left the joints swollen and tender, and ankylosis is feared.—Yours, etc.,

A CASE OF OSTEO-SARCOMA FOLLOWING SYPHILIS.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR.—Mr. N. O., a lawyer and an athlete, aged about 35 years, who had suffered from syphilis six years previously, consulted me for an inflammation on the upper and outer part of his right leg,—apparently due to periostitis.

This gradually developed into a very painful, hard swelling on the outer aspect, just below the knee joint. It continued to rapidly increase in size, to such an extent that it looked like a second knee, and the joint became fixed. He received Tibbi treatment, chiefly by the administration of strong purgatives every 3rd or 4th day; this caused many stools daily, and he became very weak.

From his history and the appearance of the swelling I thought the case to be one of gumma, but the gravity of his condition led me to advise a consultation and treatment at Lucknow. The civil surgeon there diagnosed osteo-sarcoma, and the leg was amputated through the lower third of the thigh. Subsequently infected lymphatic glands had to be removed on two occasions, and the patient was finally sent to Ranchi for radium treatment. Here he showed some signs of improvement for several days, but then died from sudden heart failure.—Yours, etc.,

M. ASLAM OMAR, I.M.P.
GONDA,
29th July, 1927.

SURGICAL WORK IN A MOFUSSIL DISPENSARY.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR.—The days are past when Indian patients in the mofussil dreaded surgical operations. The reason is not far to seek. In the old days sepsis reigned supreme, and the vivid description of the old septic days at the Calcutta Medical College Hospital forty years ago, published by an old military medical student of that College in your issue for March, 1925, shows how unpropitious

was the introduction of modern surgery into India. But those days are gone, and surgical patients often have to wait for days or even weeks for admission to the Calcutta Medical College Hospital or the Belgatchia Hospital, Calcutta.

My purpose, however, is to show that much good surgical work is being done and is possible in the Indian countryside. After twenty years of experience in the rural areas of Bengal, I am of opinion that but very few of the surgical cases seen in municipal and outlying dispensaries go on to present themselves for operation at district headquarter hospitals. Having realised this fact, I began to admit surgical cases to the Dalgram Charitable Dispensary for major operations. Dalgram

is a small village, and the dispensary is of the most ordinary type, with very small funds for its maintenance. With the help of public subscriptions I got a separate shed erected for surgical work. My staff consists of one compounder and one servant, and in many instances I had to appeal to my brother practitioners for help. The furniture consisted of a wooden operation table, a small wooden table, a small sterilizer, a stove, and an iron kettle. Only lately has it been possible to add a combined instrument and dressing steriliser to the list. Boiling was the only method available for sterilising instruments and dressings. The following table shows the number of operations performed in this dispensary for the years 1919-1926, with this primitive equipment.

Operations at the Dalgram Charitable Dispensary. 1919-1926.

Nature of operation.	No.	Average number of days in the hospital.	Anæsthetic used; general or local.	Result.	REMARKS.
Excision of tumours of various kinds, including elephantoid scrotum.	71	16	Chloroform	Cured	
Inguinal hernia	1	20	"	"	
Ventral hernia	1	15	"	"	
Ovarian cyst	1	15	"	"	Weighing 8 lbs.
Cyst in the broad ligament	1	17	"	"	
Removal of ovary	1	10	"	"	
Removal of breast	2	12	"	"	For cancer.
Old rupture of perineum	1	10	"	"	Submitted to operation for prolapsus uteri

Abscesses in other parts of the body.	793	Outdoor	None	"	
Various other operations	591	"	"	"	
Total	1,602				

A study of the above table shows the possibilities for major surgical work in *mofussil* and outlying dispensaries. The patients have perforce to be nursed by their own relatives, and also to bear the entire cost of all diet and attendants. On the other hand there are many surgical patients who cannot afford this. In my opinion government should make provision in these outlying dispensaries for at least four surgical beds apiece, with the necessary provision for the dieting and nursing of indigent patients. Such patients will often refuse to go to the Sadar hospitals, where they are away from their relatives and friends.

A further matter in which improvement is needed is in obstetric work. There is no provision in these outlying dispensaries for emergency midwifery work, such as cases of eclampsia or of abnormal labour. So far as my experience goes, the Indian villager is not in any way adverse to modern medicine, but he asks for it to be brought to his door. He will not travel to distant headquarter hospitals or to big cities in search of surgical and obstetric aid.—Yours, etc.,

AMULYA KUMAR BHATTACHARYYA, L.M.P.

INFANTILE CIRRHOSIS OF THE LIVER AND RICKETS.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR.—In reply to the question raised by Dr. L. R. Narayana Iyer on p. 175 of your issue for March 1927 with regard to my article on infantile cirrhosis of the liver, I write to say that no *post-mortem* examinations could be carried out on the cases, owing to the refusal of the parents—even of those of educated class—to permit this. Some very early cases of infantile cirrhosis of the liver might possibly be mistaken for rickets, but such early cases are never brought for treatment, as the doctor is usually only consulted when the disease is so far advanced that the parents are nervous as to its final result. Several of the local cases here have been seen by civil surgeons, who are of opinion that, if one has once seen one—or, anyhow, half a dozen—cases of infantile cirrhosis of the liver, there is no possibility of confusing it with rickets.—Yours, etc.

A. S. VAIDYANATHA IYER.

TELLICHERRY,

16th August, 1927.

A CASE FOR DIAGNOSIS.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR.—On the 14th June, 1927, I was called in urgently to see a patient living 8 miles from our dispensary, who was seriously ill. The history given was that he had been suffering from slow irregular fever and continued diarrhoea, without blood or mucus in the stools for about a month. Ginger, *asafoetida*, and other home remedies had been used and the diarrhoea had subsided. When it subsided, however, to his surprise he began to develop a generalised puffy swelling, accompanied by severe dyspnoea.

On examination, I found him to be a fairly well-built patient of about 20 years of age, of labouring class. The temperature was 97.6°F., the pulse soft but regular and 132 per minute; the respirations 67 per minute, accompanied by severe dyspnoea, for which the patient was propped up in bed. He could speak only with difficulty, and had a dry cough. With regard to the swelling of the subcutaneous tissues, it had commenced in the head and had immediately spread to the face, neck, chest, upper extremities, back, and genitalia, but the lower extremities were absolutely free from cedema. The skin over the swollen areas was glistening, and on pressure on to it typical crackling crepitus was elicited, in all areas. The cedema was of elastic

type, the skin resuming its former level when the pressure of the finger was released.

I at once thought of surgical emphysema and examined the heart and lungs. The lungs were resonant everywhere and the cardiac dulness was markedly impaired, in fact almost absent. On auscultation deep moist rales were heard everywhere all over the chest, and I could not hear the normal breath and heart sounds. Thinking the case to be one of surgical emphysema, I searched for any external wound on the body, but could find none at all. Nor could I get any history of injury to the chest or lungs or pleura. In brief, I could find no cause at all for the condition present.

Treatment therefore was symptomatic, calcium lactate powders being administered in large doses. The bowels were readily opened by saline aperients. The patient remained under my treatment for three days, but died on the 18th June. No *post-mortem* examination was allowed.

The case was a peculiar one; marked dyspnoea, entire absence of swelling from the lower extremities, and its onset with the termination of the one month's diarrhoea. I should be glad if any of your readers would make any suggestion.—Yours, etc.,

MAGANLAL D. LATTIGARA, M.B., B.S.

BILKHA DISPENSARY,

KATHIAWAR,

22nd August, 1927.

COUGH IN CATARACT OPERATIONS.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR.—The following method has proved very successful in operations on cataract patients who have coughs, and is advocated by Mr. Chawan, the Blind Relief Association's Medical Officer at Chalisgaon, East Khandesh.

Five minims of adrenalin solution are given subcutaneously before operation; or 10 minims of the same solution orally. This stops the cough for twenty-four hours and allows the operation to be performed safely. It can be repeated if necessary the next day and on following days.—Yours, etc.,

A. R. BHAT,

Chairman, Blind Relief Association.

MIRPURKHAR,

8th November, 1927.

A CASE OF SEXUAL PERVERSION.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR.—Although the occurrence of some form of sexual perversion in neurotics is a well-established fact, the following case is, I think, sufficiently foreign to the ordinary run as to warrant publication.

A patient, an Anglo-Indian male, aged 28, consulted me recently for "nervousness." Following my usual practice, I pressed him to tell me what he considered to be the cause of his illness. After some hesitation, he told me that he attributed the onset of his trouble to having inserted the horn of a rhinoceros, (presumably *R. bicornis*, as he was at that time residing in Tanganyika Colony), into his anus in order to elicit an orgasm. The insertion of foreign bodies into the anus to evoke or increase sexual feeling is, of course, by no means an uncommon procedure, but the employment of the horn of a rhinoceros to this end must be, I fancy, somewhat exceptional. Perhaps readers of the *Gazette* in parts of India or Assam where rhinoceros still abound, could throw further light on this point?—Yours, etc.,

OWEN BERKELEY-HILL,

Lieut.-Colonel, I.M.S.

RANCHI EUROPEAN MENTAL HOSPITAL,

KANKE P. O., RANCHI.

A CASE OF SWEATING BLOOD.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—The case under the above heading communicated by Lieutenant-Colonel Kelsall, I.M.S., in the October issue of the Gazette, is of considerable interest for the reason that it is, I believe, the first instance reported in this country, of the fowl-flea attacking the human host.

This fowl-flea, *Echidnophaga (Sarcopsylla) gallinaceus*, appears to be widely distributed in India, and is met with in poultry-runs and also, often in large

ECHIDNOPHAGA GALLINACEUS*DERMATOPHILUS PENETRANS*

D.A. Turkhud del.

numbers, in the living rooms where fowls are kept, especially when such places are not regularly lime-washed or treated with pulicidal remedies. These fleas can be trapped in the usual manner by letting a guinea-pig loose in the infected place, and are afterwards collected from the animal by chloroforming it.

So far as I am aware, the jigger-flea, *Dermatophilus (Sarcopsylla) penetrans*, has not yet been reported as endemic in any part of India.

Echidnophaga gallinaceus is likely to be mistaken for *Dermatophilus penetrans*. The thoracic segments are compressed in both, but the *Echidnophaga* can be very easily recognized by the presence of a patch of a number of short spines on the coxa of the hind leg; this distinctive feature is absent in the *Dermatophilus*. Moreover, in the former flea the head is small and blunted, while in the latter, it is large and pointed anteriorly.

The accompanying drawings may be found helpful in distinguishing them. The characteristic patch of spines in the *Echidnophaga* can be very readily seen under 16 in. objective; its exact position is shown in the magnified picture of the hind leg.—Yours, etc.,

D. A. TURKHUDD, M.B., C.M. (Edin.).

PLASMOQUINE.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—I have read with great interest the paper of Messrs. Fletcher and Kanagarayer, entitled "Plasmoquine in the Treatment of Malaria" in the September issue of your journal.

As I am in charge of the Medical Department of Messrs. Haverro Trading Co., Ltd., who are the sole importers of "Plasmoquine" into India, Burma and Ceylon, I would like, however, on behalf of the manufacturers, to make a short remark on the statement of the authors on p. 503.

"The tablets made as they are at present are unsuitable for use in the damp tropical climate; no sooner is the stopper of the bottle opened than their sugar-coating melts and they run together into a sticky mass."

These tablets received by the authors belong to the first output which were designed for trial work in Spain, Italy and the Balkan countries. But as the demand for trial quantities from the tropical countries also very soon arose we had to send the above mentioned sugar-coated tablets called "dragees" in order to avoid a delay in spite of the fact that we doubted their resistance to the tropical climate.

After all we are glad to inform the medical profession that the tablets of "Plasmoquine compound" now available on the market are prepared in a different way and are no more sugar-coated. They are especially made for tropical conditions and stand any climate. We hope that "Plasmoquine" in its present form which is according to the authors "a long step towards the realization of a great ideal" will soon show the beneficial results on the malaria-stricken plains of India.—Yours, etc.,

O. URCHS, M.D. (Prague).

15, CLIVE STREET, CALCUTTA.

Service Notes.

APPOINTMENTS AND TRANSFERS.

Lieutenant-Colonel W. H. C. Forster, M.B., I.M.S., Director of Public Health, Punjab, is appointed to be Inspector-General of Civil Hospitals, Burma, with effect from the date on which he assumes charge of his duties.

Lieutenant-Colonel F. Stevenson, I.M.S., an Agency Surgeon, is posted as Residency Surgeon, Kashmir, with effect from the 15th October 1927.

Major J. R. D. Webb, O.B.E., D.P.H., I.M.S., Health Officer, Simla, is placed on Foreign Service under the Indian Research Fund Association, with effect from 1st November 1927 and up to the 28th February 1928 for employment as Officer on Special Duty in connection with the 7th Congress of the Far Eastern Association of Tropical Medicine and the League of Nations Interchange of Health Officers.

Major C. M. Ganapathy, M.C., D.P.H., I.M.S., Assistant Director-General, Indian Medical Service, is appointed to act as Health Officer, Simla, with effect from the 1st November 1927 and until further orders.

The services of Captain B. S. Dhondy, I.M.S., are placed temporarily at the disposal of the Government of the United Provinces for employment in the Jail Department with effect from the date on which he assumes charge of his duties.

The services of Captain R. N. Bhandari, M.D., I.M.S., are placed temporarily at the disposal of the Government of the Punjab with effect from the date on which he assumes charge of his civil duties.

PROMOTIONS.

Major to be Lieutenant-Colonel.
J. A. Shorten, M.D. Dated 11th September 1927.

Captains to be Majors.

R. C. Phelps, M.B. Dated 28th October 1927.

B. S. Dhondy, M.B. Dated 28th October 1927.

Major (now Lieutenant-Colonel) W. M. Anderson, C.I.E., M.B., I.M.S., is granted the acting rank of Lieutenant-Colonel from 7th December 1916 to 14th October 1919 whilst serving with the Mesopotamian Expeditionary Force.

The promotion of Major R. Hay, M.B., notified in Army Department Notification No. 1334, dated the 22nd October 1926 is antedated from the 7th October 1926 to the 7th April 1926.

Lieutenant to be Captain.

G. Dockery, M.B. Dated 22nd February 1927.

RETIREMENTS.

Colonel A. N. Fleming, D.S.O., M.B., F.R.C.S.E., K.H.S., I.M.S., 8th September 1927.

Lieutenant-Colonel G. J. G. Young, M.B., I.M.S., 28th June 1927.

RESIGNATION.

Captain Subbier Annaswami. Dated 3rd October 1927.

NOTES.

CALCUTTA SCHOOL OF TROPICAL MEDICINE AND HYGIENE.

TO WHOM IT MAY CONCERN.

As our readers know, the relaxation of the regulations with regard to compulsory inoculation of infants against small-pox in the United Kingdom have been followed by a general recrudescence of the disease. At present it is of mild type, but there is no guarantee that this state of affairs will continue. In India relaxation of control is immediately—and almost inevitably—followed by severe outbreaks.

Under these circumstances the Voluntary Service Fund (Small-pox Clearance) has been formed at Home—(address: 36, Friday Street, London, E. C. 4)—to make the truth about vaccination against small-pox known to the general public. Up to date this Fund has published seven small manuals or pamphlets for general distribution; one dealing with the diagnosis of small-pox, another with its administrative control, a third with notes for medical practitioners on the disease,

a fourth summarising the general position at present in the United Kingdom, a fifth with facts for popular information, and a sixth with differential diagnosis. The seventh, and latest publication, is a small brochure with the above title, published at 1s. 8d.

To Whom It May Concern is by Dr. Wanklyn, and it is a general statement of the position with regard to small-pox and vaccination. "Our duty" he writes, "is to free ourselves from this pest. We must be absolutely and entirely quit of it once and for all. This cannot be done without general education and understanding; in that way it can be easily done. It is intended that this book shall take its place as a further contribution in support of the small-pox clearance campaign, which, under Providence, is steadily growing in volume and power throughout this country and the British Empire."

Those of our readers who are concerned in public health work may be interested to hear of this brochure, and of the existence of the Voluntary Service Fund.

MELLIN'S FOOD CALENDARS FOR 1928.

MELLIN'S Food Co., Ltd., are among the most enterprising firms in the world, whilst Mellin's food and other products are well known throughout India. Indeed one of the most amusing memories which we remember is that of a lady doctor instructing the female attendants of a Rani in one of the most backward tracts of the Central Provinces in the preparation of Mellin's food; she had had a 26-mile ride by elephant to get to the palace. Ourselves, as consultant, were only permitted to hold the royal lady's hand and to discuss her symptoms through the thickness of a very dirty cotton sheet.

Mellin's Food wall calendars for 1928 are simply splendid productions. There is one for Mahomedan doctors, 2' by 1½', illustrating in gorgeous colours the Quāba at Mecca. It is a magnificent piece of colouring, admirably executed. The other calendar is one for Hindus, and illustrates in very vivid colouring, Saraswati.

Both calendars are real works of art, and would greatly brighten the walls of a consulting room or dispensary. We are asked to state that a free copy will be sent to each of the first 500 medical men who apply to the Indian agents, Messrs. Mackenzie, Lyall and Co., 5, Mission Row, (P. O. Box No. 199), Calcutta, mentioning this journal.

Publishers' Notice.

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles will receive 25 reprints *gratis*, if asked for at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions, Advertisements, and Reprints should be addressed to THE PUBLISHERS, Messrs. Thacker, Spink & Co., P. O. Box No. 54, Calcutta.

Annual Subscription to "The Indian Medical Gazette," Rs. 16 including postage, in India. Rs. 18 including postage, abroad.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

A NOTE ON INDIAN MEDICINE.

By the late Sir CLIFFORD ALLBUTT, M.A., M.D.,
F.R.C.P., F.R.S.

(Note.—The following note on Indian Indigenous Medicine was written by Sir Clifford Allbutt in 1922, and was given by him to Sir Norman Walker. The latter made it over to Lieut.-Col. H. R. Dutton, M.R.C.P. (Lond.), I.M.S., Principal, Patna Medical College, who forwarded it to us. It is published with the very kind consent of Lady Allbutt. We think that our readers will be interested in Sir Clifford Allbutt's estimate of the ancient systems of Medicine in India.—EDITOR, I. M. G.).

THE Medicine of India has a history and a character of its own; whatever its worth it has been no mere reflection of Medicine elsewhere. If loaded with superstition and fable more heavily than the Medicine of some other countries it is so far in accordance with oriental habits of mind. On the other hand it contained much empirical knowledge which served a temporary purpose, and a plentiful collection of remedial agents, especially of medicinal plants derived from the rich flora of the land. Moreover, it had a surgery of its own which, tried even by a Western standard, was by no means contemptible. Unfortunately after its bloom it made little further growth, being confined in the hard shell of caste and tradition. Nevertheless by the missionary efforts of Buddhism, and again later by the adoption of Indian Medicine by the Persians and Arabs, it obtained no little vogue both eastwards and westwards; but nowhere in the East did it reach the standard nor the influence it attained in its native land. From early times many remedies found their way from the Indian pharmacopœia to the collections of the West (e.g., Hippocrates, Dioscorides, Galen). It has been supposed that Indian Medicine owed almost its all to the incursion of Alexander and his successors; but, although no doubt thus a wedge of Western Medicine was driven into the stagnating Indian Medicine, the Alexandrian contribution, good as it was, made a relatively small addition to the bulk of the home product. Plastic surgery, which had so active a course in the Middle Ages in the West, took its origin or at any rate its development from the Indian methods. In both cases the technique owed its vogue to the same cause, to the penal amputations of nose or ears so frequently inflicted in the later Middle Ages in Europe also. Hypnotism and the practice of "suggestion" probably took their origin in India. Five hundred years before Christ, hospitals were founded in Ceylon, whence also came many of the medicinal plants, and three hundred years before our era the Buddhist King Asoka founded hospitals for both man and animals. It is to the rich source of

the Sanscrit literature that we owe our knowledge of the origin and development of Indian Medicine which, throughout its history and growth, was largely theurgic. It was chiefly to the strong progress of its surgery that much of the virility of Indian Medicine was derived. This is an instance the more of the benefits which in the past of all peoples medicine has owed to its surgical branch.

Indian Medicine may be divided into three periods: first the Vedic, extending down to the eighth century before Christ; the Brahmanic, during which time it was dominated by priestcraft; and thirdly, the Arabian period beginning from 1000 A.D. The Vedic period had no peculiar character, it consisted largely in religious hymns and scholastic exegesis founded upon them. In its origin, of course, it arose before or with the earliest Aryan folklore (Rigveda, Samaveda, Yajurveda, Athervaveda) and depended upon a natural polytheistic religion; but contained many non-Aryan elements and much fantasy. The medicine of the Athervaveda differed somewhat decisively from that of the earlier Vedas. It was more domestic, and in this respect, and in the innumerable godlings which presided over the various bodily functions, and demons which beset man from without, reminds the reader of the early stages of Medicine in Rome. This Veda and the Rigveda are of the chief importance for Medical History. Something also of primitive Pneumatism appears in this period; as the air (breath) was regarded as the vehicle of life force. The empirical knowledge, weighted as it was by a heavy theurgy, contained little of anatomy. In those times, as ever since in India, anatomy was quenched or checked by the intolerance of dissection; but it contained some very close observation of disease, and of poisoning; no little experience of the properties of medicinal plants, of water, both for bathing and drinking, of open air treatment, and some sound surgery. In the Athervaveda, the divine powers have given way to magic and to enchantments after the kind well known in Babylon, Egypt, etc., and other sorceries chiefly directed against disease demons. At this time the great bogie was "Takman," a malignant fever which was supposed to enter into a crowd of diseases; and for which the chief remedy was the *Sama* plant (perhaps the *Asclepias syriaca*) which, besides its direct virtues which were many, had a peculiar efficacy against disease demons. It is very interesting to see how in the midst of theurgic and magical medicine the physicians, at any rate in the later Vedic time, gradually took up an independent position, in a certain antagonism indeed to the Brahmans. Thus perhaps, we may find in Indian history some explanation of the obscure growth of the independence of Hippocratic Medicine, as distinguished from the priestly medicine of Greece.

In surgical cases incantations and the use of semi-mystic herbs were made use of. Nevertheless, many diseases were clearly distinguished

and fairly described; such as scrofula, phthisis, dropsy, epilepsy, gout, heart disease, jaundice, hemiplegia, skin diseases, sexual disorders, and so forth; and some were recognised as hereditary. In the Vedas also were prescriptions for abortion, aphrodisiacs, and like purposes.

In the Brahman period Medicine has received especial attention because it was the medicine of this time which passed almost unchanged into the tradition of the Arabs; moreover, a remarkable general resemblance appeared between this tradition and the medicine of the Greeks and in certain details also. So that the earlier Indian Medicine may justly claim an originality and flexibility of its own; and moreover, was therefore the most apt to assimilate both theoretical and practical knowledge from the more advanced medicine of the West. To this resemblance to Greek Medicine no little influence may be attributed to the invasion of Alexander and to the few following centuries of trade. But the theurgic incubus was too strong and gradually medicine and even surgery fell under its hardening and sterilising domination.

In the teaching methods were some good points, e.g., a teacher was allowed to take only four to six pupils, a lesson to us! The course extended over six years and was both clinical and theoretical (textbooks). It was a maxim of their schools that a theoretical education without instruction in practice is helpless at the bedside, while on the other hand, one who has had only a practical education without theory has not the ascendancy of the best physicians. For medicine, as for Brahmanic learning in general, Benares was the chief centre. For license to practice the permission of the King was required. One of their maxims was "When a man is ill the physician is his father; when he is cured, his friend; when restored to health, his protector."

On account of the sacredness of the animal body the initial instruction in surgery was curious—the student practised incisions on fruits, he inserted probes into any perforations available, passed needles through the skin of dead animals, and upon them drew teeth and pretended to bleed from their vessels. To such straits students are reduced when denied dissection and humane animal experiments. On the other hand the surgeon was ordered to cut his hair and nails short, to put on a white vestment and to keep his body clean. At the bedside, among other "manners" he was not to enter upon any other subject than the state of the patient, not to gossip about other things nor to pry into domestic affairs. Beyond his fee he was to seek no presents unless it were a little necessary food.

The triad chiefs of Indian Medicine were Charaka, Susruta, and Vagbhata. Charaka flourished about our era; Susruta in the 5th century after Christ; Vagbhata some two centuries later, but no doubt there was a great medical tradition in far earlier times. An im-

portant MSS. written on birch bark but in good preservation was discovered in 1890 by a Mr. Bower, and is known by his name; it is attributed to the middle of the 5th century after Christ. This MSS. gives much information concerning Charaka and Susruta. Another MSS. is extant also, known as the "Macartney." From these sources we perceive more clearly that the three eminent physicians were younger champions of a medicine which, as we have said, derived from an ancient tradition, its beginnings being lost in myth, but myth with a kernel of truth. Charaka is distinguished by a more copious setting forth of his knowledge, Susruta by a drier style but with a stronger leaning to surgery. Some important sections of these have been translated into English. Of Susruta, there is a complete, but very defective, translation into Latin (Eßler, Erlangen, 1844—1850, 3 Vols., and a commentary translated and published a little later).

Charaka's work consists of eight chapters; it deals with pharmacology, diet, certain descriptions of diseases, methods of cure, physiology and psychology, anatomy, general pathology, embryology, etc. There are eight sections on skin diseases. Susruta, as we have seen, dwells more on surgery. Vagbhata is in large measure a reproduction of Susruta. They all gave their allegiance to "Ayurveda"—i.e., "the Knowledge or Spirit of Life." All later Hindu medical writers occupied themselves with these earlier authors, reproducing them and overlaying them with elaborate commentaries and a few additional matters of subordinate value. In the 16th century such derivative works were many, but unfortunately in India there was no "Renaissance." Sacerdotal sanctions overshadowed all scientific progress and not only forbade dissection but regarded all dead bodies as under taboo. Therefore, Indian anatomy could not come into existence and nominally consisted in a mere enumeration of parts of the body, in which the magic numbers five and seven prevailed. Their physiology rested upon three elements or humours—air, phlegm, and bile—and in them consisted the processes of life. From them were formed chyle, blood, flesh, fat, bones, marrow, and semen. But in all and through all was the inspiration of the Life Spirit. In the perversion of the elements lay the causes of disease, confirmed, however, by natural causes such as climate, heredity, poisons, also by sin, demons, and so forth. Diseases were classified as outer, inner, local, general, curable or incurable, physical and psychical. Diagnosis depended upon very acute observation (they noticed that the dogs licked the urine of diabetics), and upon aphorisms. As in the school of Hippocrates, and in all active schools in which necropsy was forbidden, great stress was laid upon maxims of prognosis, not undiluted by priestly and magical elements. Great stress was laid upon hygiene and diet, daily cleanliness, including the teeth, attention to the excretions,

massage and rest cures, baths, clothing and so on.

Of drugs, we have seen there were a multitude. Charaka knew of 500 healing herbs, Susruta of 760; and it is to be remarked that the Indian physicians were before the Westerns to use, both externally and internally, various mineral remedies, including mercury (Susruta) and arsenic. They had a proverb "He who knows the virtues of herbs and roots is a man; of water and fire a spirit; of prayer a prophet; of quicksilver a god." Elixirs, cosmetics, aphrodisiacs, poisons, were only too well known.

It is evident even that surgery was the strong point of Indian therapeutics; the technique was elaborate, and by its speculative fancies were so far expelled. Minute care and cleanliness were compulsory. They had a numerous collection of instruments, including the magnet for drawing out metallic bodies. Anæsthesia was induced by strong drink. Operations had to be done under favourable constellations. The Indian surgeons were remarkably successful in laparotomies, cutting for stone, and plastic operations. The Cæsarian operation was done only on the dead; of turning methods they seem to have been ignorant.

STUDIES IN MALARIA, AS IT AFFECTS INDIAN RAILWAYS.*

By R. SENIOR-WHITE, F.R.S.

Malaria Research Officer, Indian Research Fund Association. Formerly Malariologist, Bengal-Nagpur Railway.

FROM the point of view of the Malariologist a railway is a Euclidean straight line. It might therefore be thought that any attempt to control malaria along its route would be foredoomed to futility, unless powers of entry and work on surrounding property were granted. For this reason very little has in the past been attempted towards the control of malaria on railways. The railhead port of Talaimanaar on the Ceylon Government Railway was reported on by James (1912), but no anti-mosquito measures other than screening seem to have been undertaken. The Khulna branch of the Eastern Bengal Railway was the scene of a quinine campaign (Eastern Bengal Railway press, 1925), which, as might have been expected, proved futile, though some valuable statistics and experience were gained from it. Though the St. Louis South-Western Rail Road in the United States of America have conducted anti-malaria operations at a cost of \$800, (Rs. 2,400, approx.),† per mile of track with excellent results, it was not until the writer was appointed Malariologist to the Bengal-Nagpur Railway that any Indian railway made any serious attempt to

deal with the malaria affecting it.‡ It is hoped that the account of various anti-malaria operations given in the present paper will convince the administrations of the various railways of India that the control of malaria as it affects their operations is not only practicable, but economic.

I.—Malaria during Railway Construction.

Whilst it is a commonplace of the text-books that railway construction in the tropics, with its 'aggregation of labour,' is nearly always associated with fulminant epidemics of the disease, yet in the past little has been done to obviate such happenings. Medical aid to the victims has usually been liberally forthcoming, but this is of small comfort to the engineer whose work has been brought to a standstill. "A death a sleeper" is a vivid generalization on the happenings on, for instance, the building of the ghat section of the Great Indian Peninsula Railway, the Beira Railway in East Africa, the Indo-Ceylon connection of the Ceylon Government Railway, though it is doubtful if even approximate figures exist to prove or disprove such assertions.

The Amda-Jamda branch of the Bengal-Nagpur Railway, built through the hills of the Singhbhum district of Chota Nagpur in 1923-24, proved yet again what is the price of opening up communications in hyper-endemic country without the help of the expert. In the worst length the Engineer staff were doubled, in the hope that one officer out of each pair would be in a state to do duty; labour died, or bolted, in such numbers that work was finally undertaken by a Pioneer Regiment from the Frontier. In the circumstances it is hardly to be wondered at that the cost of the branch line considerably exceeded the estimate.

It was shortly after this unfortunate experience that the same Railway had to undertake another construction in notoriously malarious country, namely the Raipur-Vizianagram Railway, which is being built to serve the new Imperial port of Vizagapatam. Of the 309 miles separating the two towns, 261 have to be constructed on one sanction.

The malaria map of India, (Christophers, 1926), leaves a large patch on the route of this railway blank. 'Probably hyper-endemic hill areas.' As will be shown at the end of this section, investigations by the writer have partly filled this gap in our ignorance, but meantime it suffices to be said that between seventy and eighty miles of the route lie within 'The Agency,' as described by the inhabitants of the Northern Circars, or in 'Madras,' as used by the people of the Orissa Feudatory States.

There are malarious tracts of general evil reputation in many parts of India. The Terai of the Eastern Himalayas, the Northern slopes of the Khasia Hills behind Gauhati, Lahore Cantonments (Mian Mir), most of Chota Nagpur in Bihar and Orissa, the foot of the Nilgiris, (where, incidentally, the station staff of Kallar leave for healthier quarters by the last train of the day and are brought back by the first train in the morning), to name but a few, are all notorious for their 'feverishness,' but it is probable that no locality in the whole Indian Empire has such a dreadful reputation as 'The Agency.' "Completed Agency Service" is an asterisked qualification in the Madras medical cadre list! The planter goes to the Duars expecting malaria, the Forest Officer of Singhbhum faces it with some equanimity, but 'going to the Agency' in Northern districts of Madras is a matter for bated breath! Though it may be legitimately argued that 'wind-up' to this extent has a psychological effect in inducing any attack to assume an ultra-serious nature, there is still no doubt that this is the largest hyper-endemic

* Paper reprinted by kind permission of the Editor, *Technical Papers, Indian Railway Board*, from *Railway Technical Paper No. 258*. Mr. Senior-White's paper is of such importance that we consider that it should have much wider publicity than would be given by its publication merely as a technical paper with a limited circulation.—En., I. M. G.

† Figures published whilst this paper was in the press claim a 97 per cent reduction in malaria incidence in nine years' work [van Hovenberg, *Railway Engineering and Maintenance*, XXII, 382; abstract *U. S. Public Health Reports*, XLIII, 878.]

‡ The E. B. R. have recently put up proposals for following the lead of the B. N. Ry., vide E. B. R. press report of 15th March 1927, "Methods of Malaria Control."

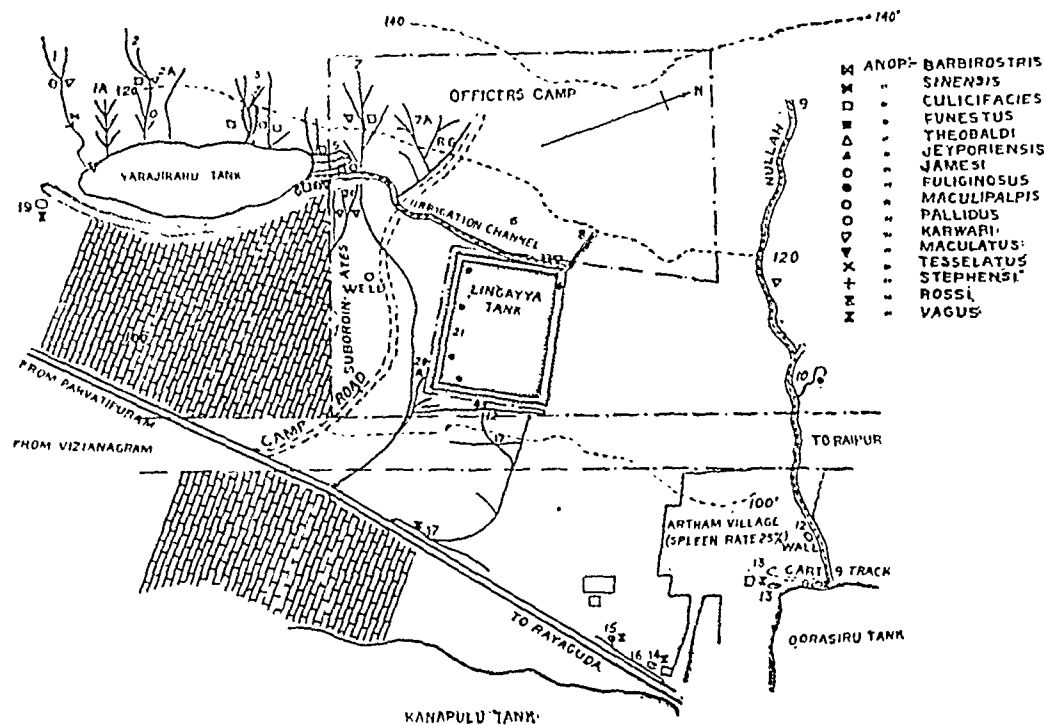

tract in the Empire. How serious conditions really are is set forth in cold statistics in the report of Perry (1915).

The experience of the surveys for the Raipur-Vizianagram Railway was fully confirmative of the deservedness of the evil reputation of this district. (a) The whole route was surveyed by officers of the now defunct East Coast Railway in 1883-86. Two years were spent on reconnaissance before a route was found across the Eastern Ghats practicable for a railway, two years more in actual survey. The records of this party are apparently lost, and what casualties they suffered is not known, but the writer stumbled on the grave of one of the engineers of the party, twenty miles south of the Madras frontier, in December 1926, being the next occasion since 1886 when the whole route was traversed by railway officers. (b) In 1897 a further survey was started from the southern end, also by the East Coast Railway. This party broke down from malaria 99 miles from Vizianagram, or after traversing barely forty miles of the hyper-endemic zone. (c) In 1907 yet another party essayed a re-survey, but likewise broke down after achieving only two miles more than their predecessors of ten years previous. (d) Lastly, in 1923, the twenty-four miles across the summit of the

medical arrangements he pitched a large base camp four miles north of Parvatipuram between a hill foot and a tank. All went well. The rains arrived, streams rushed down from the hills above, and nothing happened. Early in September of that year the writer was appointed, and proceeded to Parvatipuram. He had been assured in Calcutta that the unhealthy country did not begin for at least ten miles north of this base camp. The rains were practically over and the whole area at the hill foot was a mass of seepage, which with the cessation of actual precipitation was starting breeding. The grass of the camp was squashy under foot, and footprints filled up with water, which swarmed with larvæ, mostly *A. culicifacies*. Within a quarter of a mile of the camp was a village, spleen rate 25 per cent. It was obvious that, with the approaching hatching out of the first generation, an outbreak was impending. Accordingly, before any further work could be undertaken, this ill-placed base camp,* which with its stores was too large to move, had to be protected. The plan for this, as typical of the protection scheme subsequently evolved for actual construction operations, is given in Chart II.

Even before drains could be cut promiscuous oiling of the principal areas was undertaken, the drains

CHART II.

range were again re-surveyed. By this time the railway from Vizianagram to Parvatipuram (48 miles) was opened, and motor transport was available to a certain extent. Three months only, January to March, were spent in the field, and the Engineer in charge of the party left railhead with all his staff duplicated. On completion, only 25 per cent. were effective.

Meanwhile, another survey across Jeypore State to the west of the line under consideration had cost the lives of two officers of the party.

Such was the record when actual construction was sanctioned in 1925. Work was started from both ends, but the Northern end, from Raipur, (District IV), being in healthy country for the first thirty miles, need not be considered at present.

The District Engineer for the Southern end, (District I), took up his station in May 1925. In consultation with the Assistant Surgeon in charge of his

being cut subsequently to concentrate the seepage water and to dry out the intervening land. It will be noticed that hill foot contour drains were not used. They would have been far better, and far less expensive in upkeep than the herring-bone system put in, but speed was in this case the essence of the contract. Labour, at that time, was scarce and poor, as no actual importations had yet been made and the local labourer is disinclined for hard work of any kind, whilst contour drains would have involved difficulties with the stony hill foot soil. As it was, fresh seepages were always breaking out between drains, involving the putting in of additional ones, as is seen by those marked 'A' on the plan. However, the crude scheme worked, and an outbreak in the camp was averted, although the nearby village,

* To the layman the site would appear excellent. It was in a mango tope, with good water supply, which only proves the necessity of expert camp siting.

SPL

Porosurampuram 10 Gunan

The information thus elicited was fully confirmatory of the appearance and reputation of the district, though disturbing to the engineers, who imagined that in working up to mile 86 they were running through fairly healthy country, halting at the edge of the real danger zone. A five mile length was discovered, (mile 62 to 67), where the spleen rates are as high as they are likely to be anywhere in the world.

Armed with this information the Acting Chief Medical Officer and the writer in conference with the heads of the Engineering Department and the District Engineer, proposed that when actual work was started the contractors should not be allowed to string out their labour all along their lengths, as is apparently the invariable custom in railway construction, but should be forced to concentrate them in camps, at the rate of two camps per three mile length, on sites capable of anti-mosquito protection, to be selected by the Malarialogist, in consultation with the District Engineer in respect of convenience for work, where practicable. This method of working was novel to the contractors, who are usually men from Kutch, of no particular education, and accustomed to use up their coolies as they do their tools, with no concern about their health until this reaches a point when it affects them financially, for which reason a certain amount of opposition was incurred, and for a considerable time unauthorized camps kept springing up, which had to be dealt with. The location of the sanctioned and protected camps on the length is shown in thick circles on Chart I.

It was manifestly impossible to carry out a detailed mosquito survey of the whole thirty-eight miles prior to choosing sites, and such had to be selected 'by eye' in the first instance. Detailed surveys of selected sites were then undertaken as fast as possible, and protection plans for each drawn out and formulated. Owing to the necessity of providing each of a dozen contractors with at least one camp from which he could commence operations and locate his coolies, who were commencing to arrive, much dodging up and down the route was necessary. This, in a country with unbridged roads in so vile a state of disrepair as North Madras was very wasteful of precious time. In spite of a repair shop at base camp, cars were continually going out of action through the appalling tracks over which they were run, whilst late rains often brought down floods which rendered all or any of the unbridged rivers impassable for a day or more. Had more than thirty-eight miles been commenced at one time it would have been impossible to keep pace with demands for camps and simultaneously oversee actual drainage and oiling operations, indicating that in future, camps should be sited and protection therefor organized well ahead of actual importations of labour. As it was, contractors located in some comparatively healthy lengths had to be left without protection for some weeks, with more or less ill effects. It must, however, be remembered that all this organization work was a new thing, without any precedent save Panama, and there was no financial liberty on the scale of the great American undertaking.

Immediately following survey and drainage operations it was necessary to organize oiling. This was done with crude oil, applied to running water by swabs previously soaked in it staked in the channel or by spraying machines of the 'Four Oaks' pattern. Much of the country was very rough, and the coolie needed a free hand for movement. The type with the self-contained pump with which pressure is raised prior to being carried was therefore preferable to the type in which one hand pumps whilst the other directs the spray. The 3-gallon capacity machine, charged, was also found rather too heavy for use in rough country, and the 2½-gallon machine was preferred. Its smaller capacity, however, involves greater

waste of time whilst further supplies are brought from the sub-dépôt established at each camp. Machines constantly needed minor repairs, and the staff was placed under an ex-sergeant of Royal Engineers as chief inspector, which class of man alone seems to have sufficient organizing capacity and initiative to carry out the details of a rather complex organization.

As soon as possible returns were started to keep check on the results of the work. These were never completely satisfactory, and, in the writer's opinion, never could be so without undue expenditure. The medical staff of a construction consists of an Assistant Surgeon with each District Engineer, and one Sub-Assistant Surgeon per twenty mile length, and it is manifestly impossible that each man should visit each of a dozen camps daily and make out a sick return, in addition to running an out-patient dispensary at his headquarters. All that could be arranged for was that each contractor should submit a daily return of the approximate number of coolies in each camp and the number of cases of fever occurring during the day. *Bokhar* is an elastic term covering many other diseases than malaria. Again, great difficulty was experienced in getting the contractor to record only fresh cases each day, and in several cases deliberate falsification was proved, in the hope of getting enhanced rates of work such as are sometimes paid in ultra-feverish country. Finally, reliance in any form on the contractors had to be abandoned, and resort had to be made to the Sub-Assistant Surgeons obtaining 'figures' once each week by enquiry from the coolies themselves. In any case, one thing is certain, that the statistics do not err on the side of under-statement!

Even against this handicap, the results amply justified the measures taken. For ten months for which records had been obtained up to the time of the writer's departure for other work, the daily incidence of malaria never reached 2 per cent. of the total strength, a figure which the engineers considered negligible. It may be claimed, in fact, that construction through this hyper-endemic tract has proceeded with a lower morbidity from malaria than any large engineering work hitherto undertaken in India. The mortality from the disease has been nil.

TABLE II.

Monthly Malaria Incapacitation Incidence, Raipur-Vizianagram Railway, District I.

Month 1926,	Man-days.	Cases.	Daily per cent. attacked.
February	24,444	438	1.79
March	39,966	613	1.53
April	41,837	793	1.89
May	32,730	427	1.35
June	35,375	636	1.80
July	40,309	515	1.28
August	47,355	683	1.44
September	48,347	425	0.88
October	82,258	157	0.19
November	94,059	288	0.30

These results, moreover, were not obtained at any inordinate cost. Once the organization was got into working order, which took between three and four months, the upkeep charges, which consisted of the salaries of the inspector and his assistant, the drain maintenance and oiling coolies' pay, oil, and the running of a vanette car for travelling, together with a proportion of the cost of the malarialogist and his establishment at headquarters, only amounted to

Fig. 1.—The area in the foreground was originally a deep borrow pit, drained by a straight channel carrying a stream. The photo shows conditions at the close of the Monsoon. *A. maculatus* just starting to breed in large numbers.

Fig. 2.—Camp mile 55, showing typical huts used by construction coolies, and river margins breeding *A. cuticifacies*.

Rs. 18 per mile of construction per month, a negligible amount in the vast sums involved in railway construction.

Several instances occurred indicating what would have happened had the ordinary construction methods been followed in such country, and, I think, proving the financial justification for anti-malaria measures on work of this nature. (i) Camp Rambudrapuram at mile 60 had to be located too near the village of that name, with a spleen rate of 60 per cent. There was a particularly contumacious contractor on this length who during an interregnum flatly refused to carry out the orders of the malaria section. The Assistant Engineer acting in charge of the District engaged him in a correspondence instead of taking instant measures. A fortnight was wasted by all concerned except the mosquitoes! An outbreak occurred and about forty coolies bolted. (ii) A camp, (not shown on the map), was put up at mile 62½, mainly to house coolies engaged in transport of stores across the Solawa nullah nearby whilst it was impassable for lorries during the monsoon. Owing to a misunderstanding it was not protected immediately. The fever rate was 12½ per cent. On starting protection it fell in two months to 3 per cent.

Railway construction has the further disadvantage from the malariologist's point of view that conditions are never static. The camps were surveyed and protected on the original lie of the country. In few did conditions as shown on the plans endure for long. Streams were diverted for engineering purposes, embankments caused pools behind them, seepages were exposed by borrow pits. Fresh breeding places were thus created almost in a night, and once the writer had ceased to reside in and devote his whole time to the district, the sanitary inspector had to meet every emergency as it arose, without waiting for the next visit of the malariologist.

Only a man of exceptional initiative and experience can successfully fill such a post of Sanitary inspector, and though, on subsequent inspection, the writer at times found that water which could only have produced harmless species like *vagus* was being treated, it was extremely rarely that he found a dangerous breeding place overlooked. Such never failed to declare its presence by a rise in the fever rate of the camp affected within a fortnight. A small outbreak at camp mile 59½ was traced to some seepage on a hill-side in dense bush that had been overlooked in the original survey. It was then just dry, but spraying all the huts after temporary evacuation was necessary to deal with the infected anophelines which they harboured.

It must be also remembered that the majority of the coolies engaged for construction work are infected prior to arrival, and number numerous gametocyte carriers among them. Many camps showed one or two days enhanced malaria incidence following rain or cold snaps. In every case absolutely no breeding could be found around them, nor anophelines in the huts. They could only have been in the nature of general relapses. How little the *kutcha* huts used by coolies on constructions afford protection from wet or cold and how suitable they are, with their leaf-plait walls, for harbouring anophelines, Fig. 2 shows.

A failure may be as instructive as a success, and the following is an account of one such. Thirty miles north of Parvatipuram lies Rayaguda, one of the two small towns of the Vizagapatam Agency Tracts. The spleen rate of the town is in the neighbourhood of 40 per cent., which is low compared with many of the surrounding villages. The Government dak bungalow is nearly a mile away from the town, and has a most evil reputation amongst touring officers of Government. An Assistant Engineer with staff took up his quarters in and around it at the start of construction, and suffered no ill effects during the monsoon. It was not until early in

December that this place could be attended to. The bungalow is situated on a cape of high land, with the gorge of the Rayaguda river, (Fig. 3) on one side and a deep ravine with nearly vertical cliffs on the other, (Fig. 4).

The river gorge breeds a certain amount of *A. culicifacies* in backwaters with *Spirogyra* after the rains subside, but the ravine is much the more dangerous, being full of seepage springs at the foot of the cliffs, which collect into a small stream with a *Ranunculus*-like plant interwoven with *Spirogyra* growing thickly on its edges. An irrigation channel, grass edged, takes off and follows the stream, and some of the rice fields near the mouth of the ravine are perennially wet through seepage. The whole area swarmed with *A. funestus*. The measures taken consisted of clearing off all the marginal vegetation of the stream, (this had to be repeated almost weekly), and rough weeding the seepage area, so that the oil had a chance of reaching the larvae, but the rice field, with unreaped stubble over mud so soft and deep as to render it largely impassable, defied protection by oiling. That a certain amount of improvement was affected is shown by the fact that the engineer and his staff escaped serious malaria, but the health of the former gradually went downhill, and he had to be invalided.* To test the efficacy of the control the writer slept without a net for one night only in the middle of the monsoon in the dak bungalow, and contracted benign tertian malaria, but the oiling was two days overdue owing to flooded rivers rendering earlier arrival impossible, and as the oil was being washed away almost as soon as applied at that time of year, it is possible that more larvae than usual were managing to breed up. The place can only be dealt with efficiently by considerable engineering works involving either transforming the ravine into a lake by a series of dams to bury the seepage, or the lowering of the entire ravine level to dry out the margins of the stream and get the seepage into the main channel, (Fig. 4). As the whole bottom is sand, this latter would need never-ending upkeep. In addition the rice land containing seepage would have to be acquired and effectively under-drained. Here we have an instance where temporary methods of control fail.

The assistant engineer stationed at this place was moved, when failure was proved, to a healthy and protectable site north of the town.

The Anophelines of the Vizagapatam Agency Tracts.

The Anophelines of the district above described are as follows:—

A. sinensis: *A. barbirostris*: *A. vagus*: **A. culicifacies*: **A. funestus*: *A. karwari*: **A. maculatus*: **A. theobaldi*: *A. pallidus*: *A. fuliginosus*: **A. maculipalpis*.

Those marked with an asterisk were treated as potential carriers and attacked in drawing up control plans.

All of these have previously been recorded, from the Jeypore Hills to the West of the valley used by the railway, by Perry (1915) except *A. maculatus*. Compared with Perry's list, the noticeable absentee is *A. jyporiensis*, but this species was never encountered, which is remarkable, as I have subsequently turned it up on the Coast at Vizagapatam.

* Without laying claim to any particular psychopathological knowledge, there seems to the writer to be something particularly depressing in the benign tertian strain of the Agency, in its effects on Europeans. I have watched the effects of only one attack each on three Europeans of the railway staff, and it is extraordinary how persistent are the mental effects of quite short and mild attacks of malaria, long after the actual infections were past.

The malaria carrier of the district *par excellence* is *A. funestus*. It swarms in every suitable streamlet, even in quite large rivers when these have shrunk to meandering side channels over sand where such touch the grass-covered main bank. The species is not found out on the main floor of the valley far from the hills, and the map, (Chart I), shows how the spleen rates decrease away from the hills. Pressure of administrative work left no time for dissection, but I found zygotes in one out of eight (12½ per cent.) taken in my assistant's tent outside Rayaguda dāk bungalow when surveying this spot in December 1925. Odd specimens used to be found in Artham base camp, around which it did not breed, which were traced to a nullah two thousand feet to the northwards, until this was also oiled.

In this district *A. culicifacies* seems to play quite a minor part in malaria causation, in fact it appears to be far more the anopheline of epidemic than of endemic malaria. As the rivers fall very low about Jahuary, small embayments in their sandy margins

ing with larvæ of *culicifacies*. Possibly the wind through the gap in the hills shown on the map to the east carried adults into the camp, though the river approaches considerably closer to other camps without affecting their health (Fig. 5).

A. maculatus.—The distribution of this species is so patchy that, could the underlying reason be elicited, important information on the controlling factors in anopheline distribution would be gained. It was, of course, impossible to undertake detailed researches, and pH values alone afforded no indication of differences, but throughout the whole 38 miles *maculatus* was only found around the camp at mile 63, but here it swarmed in several streams. Fig. 6 shows a *maculatus* stream and Fig. 7 one containing *funestus* only. The two are less than two miles apart, and appear of identical type.

The only difference noticed was that the former was actually on the spurs of the main range bounding the valley to the west and running back to the 3,000 foot plateau, the latter on a small chain of hills

NOTES.—The very small number of crescents found agrees with the remark of Perry (1915) that in this country "crescent formation is by some means checked."

Perry's figures are complicated for comparison purposes in that they did not diagnose rings. His percentages appear to be about 14, 40 and 46 for the three parasites. In other words, at the foot of the Jeypore Hills there is apparently more M. T. and less Quartan than in the hills themselves, but owing to M. T. (other than crescents) being normally seen as rings only, the difference is probably not a real one.

swarmed with this species. The whole bank of the river shown in the distance in Fig. 2 bred heavily. Oiling so great a length was impracticable, and I watched events with apprehension. Yet no outbreak took place here. The only source of *funestus* nearby, a tributary nullah, was under control. Possibly the known higher affinity (Perry, 1915) of this species for cattle over man deflects it in villages which, like all those of the Agency, swarm with cattle kept close to the houses. One outbreak, in May, however, was unquestionably to be attributed to *culicifacies*. At this time of year all but the main rivers of the valley are dry, and the camp on the site of Jimidipetta station, (mile 68), was at this time going 1½ miles to the Nagavali River for its water. In this direction lies Banapuram village, with a spleen rate of 18 per cent. only. In drawing up plans for this camp some months previously I had felt quite safe in neglecting the river. Making search for the cause of the outbreak, relict pools in the sand of the river bed were found swarm-

isolated from the main range by a narrow back valley.

A. karwari.—The district is singular, as far as I am aware, in the wide distribution of this species without the closely related *maculatus*. Perry, who also found this species, makes no remark on this point, which has been checked out sufficiently, I think, to be taken for a proved fact. As the species, however, was nearly always found in company with *maculipalpis* attacking the latter obliterated the former, and so there was no opportunity of checking Hacker's (1919) hypothesis that *karwari* is of no practical importance as a carrier.

A. fuliginosus.—The last remark indubitably applies to this species also, at least as regards this district. Chart II shows that it swarmed, mainly in the cold weather, in Lingaya Tank in the very centre of Artham base camp. Examination of a very similar tank close to the village of Siveni, (mile 50), where

the spleen rate is *nil*, showed this also to be swarming with *fuliginosus*. Siveni is on the road from the north, and numerous infected persons must pass the night hereabouts. I decided, therefore, to neglect the *fuliginosus* breeding in the base camp, with the happiest results. Further instances of its apparent non-importance as a carrier in other parts of India will be given in subsequent sections.

A point which struck the writer very forcibly was the relatively very small amount of breeding for the very high spleen rates found. There is, of course, no medical aid normally available to the villagers of these wilds. An infection once acquired goes on until natural immunity checks it. By this time the patient has been a gametocyte carrier for months or even years, and with villages full of such the ratio of infected specimens to the total carrier-species population is probably very high. In every sense, then, those villages are hot-beds of malaria, and every effort was made to locate camps as far distant from them as possible. The danger of using resthouses the verandahs of which when not occupied, (and I have found the last entry in the visitors' book of Agency resthouses to be two years old), are used by passers-by for shelter is considerable, as pointed out by Perry, owing to the high number of gametocyte carriers in the country. Such dangers, however, cannot always be avoided.

far south, and for it should be substituted the barring of hill foot endemicity. The hyper-endemic area commences ten or fifteen miles further north than the map shows. In Table III are given spleen rates taken in villages where halts were made during a rapid traverse of the whole 260 miles in December 1926, which drives one line of survey clean across the blank area. This was only a preliminary inspection made hastily to enable some idea of the country from the malaria point of view to be acquired before the writer severed his connection with the railway. Enough was seen to make it obvious that the whole length would well repay intensive study, and that, considerable as have been the difficulties encountered during practical control of the disease further south, they are slight compared with what will be encountered when the actual crossing of the Eastern Ghats is undertaken in the near future. As no malarialogist, and few other Europeans, have ever previously crossed the ghats by this route, some description of the country may not be out of place.

From mile 86 the actual approach to the summit, (1,300 feet), is up a narrowing valley, sparsely inhabited by aboriginal tribes. It is this valley, ten miles in length, that has been responsible for the disasters to the survey parties. The writer believes that his spleen rate of 92 per cent. in twenty-five children at Pedda Brindabari, (mile 96), near the

A second point which deserves mention in connection with railway malaria is the harmlessness of borrow pits when freshly excavated. Only *A. vagus* is at all common, as would be expected from the muddy nature of the contained rain water. [Old borrow pits which have become filled with vegetation are another matter and are dealt with in a subsequent section]. The exception to this statement is when the pits expose seepage springs near their bottom, when *A. funestus* may occasionally find entrance. Borrow pits are mainly dug in dry weather, when seepage does not occur. They fill with the rain of the following monsoon, and when the seepage again arises, it is hidden in the rain water. Which pits are possibly dangerous, therefore, it is impossible to be certain about. In hill foot localities, therefore, where seepage was possible, such pits were treated with cresol, on the chance that seepage might be mixed with the rain water and let in *funestus*.

Data towards filling the blank area on the Malaria Map.

Table I gives data enabling the southernmost portion of the blank area on Christophers' (1926) map to be filled in. Incidentally it may be mentioned that his dark blue area (hyper-endemic) is brought too

dāk bungalow of Balugar, is unique in the number of children found for such a rate.* Usually such extreme conditions are productive of few children, (cf. Boodaguda mile 79, Table I), but these aboriginals appear perfectly healthy, and their villages are among the neatest and cleanest in all India. The houses are in two long lines, of uniform roof height, facing inwards to one another, about one hundred feet apart, the cattle sheds occupying the central area, which is swept by the united women of the village daily. Back of the houses, within the panther fence universal in these parts, are gardens. That their immunity even in adolescence is only partial, however, is indicated by our finding, in the jungle, a very sinister little temple, which the headman explained was the shrine of the fever devil, only invoked when malaria was bad. The image of the devil was in bad repair, however, suggesting that the season had been a normal one!

The intense malaria of this valley is due not only to small deeply cut nullah streamlets, but also to the

* Whilst this paper was passing through press, Kligler recorded a 94.2 per cent. rate among 139 children in Palestine, [*Jo. Prev. Med.*, I, (2) 155, (1926)].

main stream draining the centre, the Kedapara, the sandy margins of which were swarming with anophelines, whilst in the last few miles below the summit the flight range from the main stream easily reaches the foot of the enclosing mountains. In other words, there is not a single spot in the upper reaches of the valley which is safe, save only in the monsoon, when all water is in flood. At that time of year, however, travel in this country is impossible.

Beyond the summit lie ten miles of open plateau, irrigated from little foot hill streams, and only less intensely malarious than the approach, on which is situated Bissemkattak, the last administrative outpost of the Madras Presidency. Meaning 'Poison Fort,' this place is literally a name of terror down on the Coast, and this is hardly to be wondered at, for in addition to its unhealthiness it is more or less isolated by flooded rivers for several months each year, and it has no telegraph. For a small town of several hundred people the spleen rate of 60 per cent. is sufficiently remarkable. Most of the inhabitants are descendants of Telugu immigrants from the plains. The writer's value of the spleen rate taken on a small number of children agreeing closely with that of the Government Sub-Assistant Surgeon stationed here taken in a much larger number, I have less hesitation in including in Table IV the latter's figures

and 1914) on malaria in the Central Provinces. Comparison of the table with Christophers' map shows the effect of crossing, between Suamar and Arand villages, the dark blue patch shown south-east of Raipur, and shows how sharply demarcated the boundaries of a malarious zone can be. These here coincide exactly with those of the *sal* forests, and it was just on this length, as adumbrated in an official report by the writer eight months before it happened, that the construction of District IV of the railway was considerably hampered by malaria in the autumn of 1926. No control measures were in force on this district, and coolies were encamped wherever they wished.

II.—Malaria in Connection with Tunnelling Works.

Saranda Tunnel, on the main line between Calcutta and Bombay, 218 miles west of the former, in the Singhbhum District of Chota Nagpur, is driven through the range from which it takes its name at an elevation of about 1,600 feet. The surrounding country is heavily forested, sparsely inhabited by aboriginal tribes, Hos, Mundas and Oraons, the feverishness of whose jungles has been the chief reason for the preservation of their racial entities. So wild, indeed, is the neighbourhood that even to-day elephant sometimes roam round the station, and it was a mile

for the town and for all villages within a five mile radius, which show that even in such hyper-endemic country the intensity of the disease is quite patchy.

Beyond the Bissemkattak plateau the country is again of the type existing below, forest or scrub-covered hills with rice in the valley bottoms, and so continues right up to the Madras frontier. Crossing this into Kalahandi Feudatory State heavy *sal* forest is entered, in which spleen rates are equally high, but in ten miles, leaving the forest and entering the plains sloping down to the Tel River, the rate drops abruptly to 8 per cent. This healthy country extends to the end of the blank patch at the Tel River, which is the boundary between Kalahandi and Patna States.

In Table V are given the detailed spleen rates for the seventy miles of the railway which will lie within the Central Provinces between the Jonk River and Raipur, for amplification of Kendrick's reports (1911

west of here that the Bombay Mail was completely derailed in collision with an elephant soon after the tunnel was opened.

The original tunnel was constructed in the eighties, and the malaria rate, though no records exist, appears to have been extremely high. It is said that mortality and bolting among the labour so disorganised the accounts that the gangs were paid, shift by shift, as they emerged from the workings. Several of the Cornish miners who formed the subordinate tunnelling staff died of malaria, or more probably of blackwater, for which the district is notorious.

For many years after its construction the tunnel area remained uninhabited, and speedily reverted to its primeval isolation. Then, with increasing traffic, a passing place on the single line was opened about half a mile west of the tunnel. This proved unsatisfactory for several reasons, not the least of which was the

Fig. 9.—West Portal, Saranda old Tunnel, showing track side drains breeding *A. theobaldi*.

Fig. 10.—Blackwater house, East portal, Saranda Tunnel. The railway cutting shows in the right foreground.

Fig. 11.—Posoita Station—Spleen rate 86%. The borrow pits mainly responsible for the *funestus* breeding are in the centre of the photo. (Vide Fig. 12.)

Fig. 12.—Near view of part of connected borrow pits at Posoita Station (vide Fig. 11). A typical *funestus* breeding place.

extreme malariousness of the spot chosen. The reason for this will appear subsequently. Shortly after the War, with the post-war boom in iron ore traffic, a passing place to shorten the ten miles in maximum grades which separate Posoita and Gailkera stations became imperative, and Saranda 'station,' which does not appear in the public time tables, and which is really only a short length of double line to pass trains on, was brought into existence at the east of the tunnel. The effect of residence in such a place is seen in Table VI.

With further increase in ore traffic, it became necessary to double the thirty-eight miles between Manharpur and Chakradharpur, whence doubling already existed to Tatanagar, the junction for Jamshedpur, and this involved duplicating the tunnel. The works were let on contract to a European firm in 1925.

Now tunnel construction differs from ordinary railway building in that it involves the employment of a large amount of highly paid skilled labour, owing to

labour had practically disappeared, and with local aborigines taking their place as coolie labour, the next year's records open with a malaria rate of 8½ per cent. only, which, as might be expected, gradually fell to just over 4 per cent. in May.

It was in that month that the writer was instructed to take charge of the malaria situation here, with a view to preventing the happenings of the previous fever season. Even in May there was a good deal of water about. The existing tunnel is perennially wet, and from the west portal there is a never failing running drain down each side of the track. These were full of water cress, and swarmed with larvæ of *A. theobaldi*, (Fig. 9).

Further to the west, around the site of the original abandoned station,—'Old Saranda'—were numerous breeding places of *A. funestus* and *A. culicifacies*. The survey map, (Chart III), does not need any very detailed study to see why malaria was from the outset so appalling at this site.

the amount of machinery in use. The Ooriyas and Chhatisgarhis who furnish the bulk of ordinary earth-work labour are unfitted for such duties, which are undertaken by Bombay-side men and Punjabis. Men of this type then formed the mechanic class on the tunnel works, with originally some Chhatisgarhis for purely coolie labour. Many of the mechanics came to the works from the Khyber Railway, and it is possible that they had a good deal of malaria in them to start with.

What might have been foreseen, happened. The works were opened in August 1925, and malaria was at once responsible for an incapacitation rate of 21 per cent. Though this fell to 18½ per cent. in the next two months, thereafter it rose with the onset of the true malaria season until the records for the year close in the second week of November with a 34 per cent. sick rate, at which time the Assistant Surgeon died of blackwater and the office staff were so disorganized that no further records were kept until the end of the epidemic in March 1926. By this time the Chhatisgarhi

The locality readily divides itself into three parts; Saranda station, open since 1919, with a small permanent population of railway employees, engaged in working the passing place on the open line; the main camp, more or less on top of the original tunnel; and old Saranda, a camp in connection with the deep rock cutting approaching the western entrance to the new tunnel, situate in and around the abandoned buildings of the original station. The whole extends over about a mile and a quarter of the line.

The spleen rates as they existed in July 1926 are given in Table VI.

These indicate in the first place how much more heavily malaria falls on the plains child than on the aboriginal of the same stage of life. Also they show that the main camp was distinctly the most unhealthy of the three areas, and seem to indicate that here conditions were almost too much for the aboriginal, whose rate nearly equalled that of the plains races. Among the latter, however, are included a few Gurkhas, children of chowkidars, and it was obvious that of

all the melange of races on the works, the Gurkha was by far the worst sufferer. It was really astonishing to see the state of wreckage to which malaria had reduced these men and their families.

Naturally, blackwater fever was present. Three cases, two fatal, occurred in the year of working. One was the Assistant Surgeon employed by the contractors, previously mentioned; the other was a child aged five, whose case the writer was fortunate enough to see within twelve hours of the onset, and follow to the fatal termination. As always happens with blackwater, however, none of the apparatus one would like to have employed was available. The case notes are given in an appendix to this section. A fourth (also fatal) case of blackwater occurred later before the malaria was got under control. Two out of the four cases occurred in one hut (Fig. 10), being father and child. This hut is situate immediately above the cutting at the east end of the old tunnel, above track side drains running with seepage for at least six months of the year, and with other perennial breeding places nearby. The drains at the east end of the tunnel did not contain watercress, and the species found was *A. culicifacies*, not usually associated with blackwater cases.

Old Saranda presented a more difficult problem. The track side drains emerging from the tunnel at its western end, originally full of *theobaldi*, were nearly completely rid of it by cleaning out the watercress, to the vast disgust of the coolies, who used it for food. Weekly oiling then rendered the twin streams absolutely sterile. The series of deep pools in the new cutting, which were unapproachable in many places for examination owing to its vertical sides, and which only awaited the resumption of work after the monsoon to disappear in the course of ordinary operations, were fortunately found, in the few places where their surfaces were approachable for examination, to be breeding *rossi* only. A swamp below a culvert, (No. 13), in the course of the track sides drains where these leave the line and are continued as a definite stream south of the railway, was dried out by a through drain, and the oil coming down from No. 6 drains above completed the control; but a dam, (No. 11), with a swamp (No. 10) on one side and a feeder stream, (No. 12), meant quite considerable engineering works if they were to be rendered sterile. These would have been undertaken had there not been worse nearby in the shape of a dam, (No. 8), partially broken down, and so with a permanent swampy floor breeding *culicifacies*

Chart III gives a plan of the breeding places of the three areas.

Owing to the very large amount of work to be done, it was decided to limit operations to the quarter mile circle around each of the three inhabited areas. Of those affecting Saranda Station; the stream, (No. 5), was trained, and its margins, oiled; the track side drains, (No. 6), were cleaned out and oiled; and drain 16 carrying the pump outflow from No. 2 shaft canalized, and the spring causing swamp 17 put into a short drain leading into the latter, the whole being oiled.

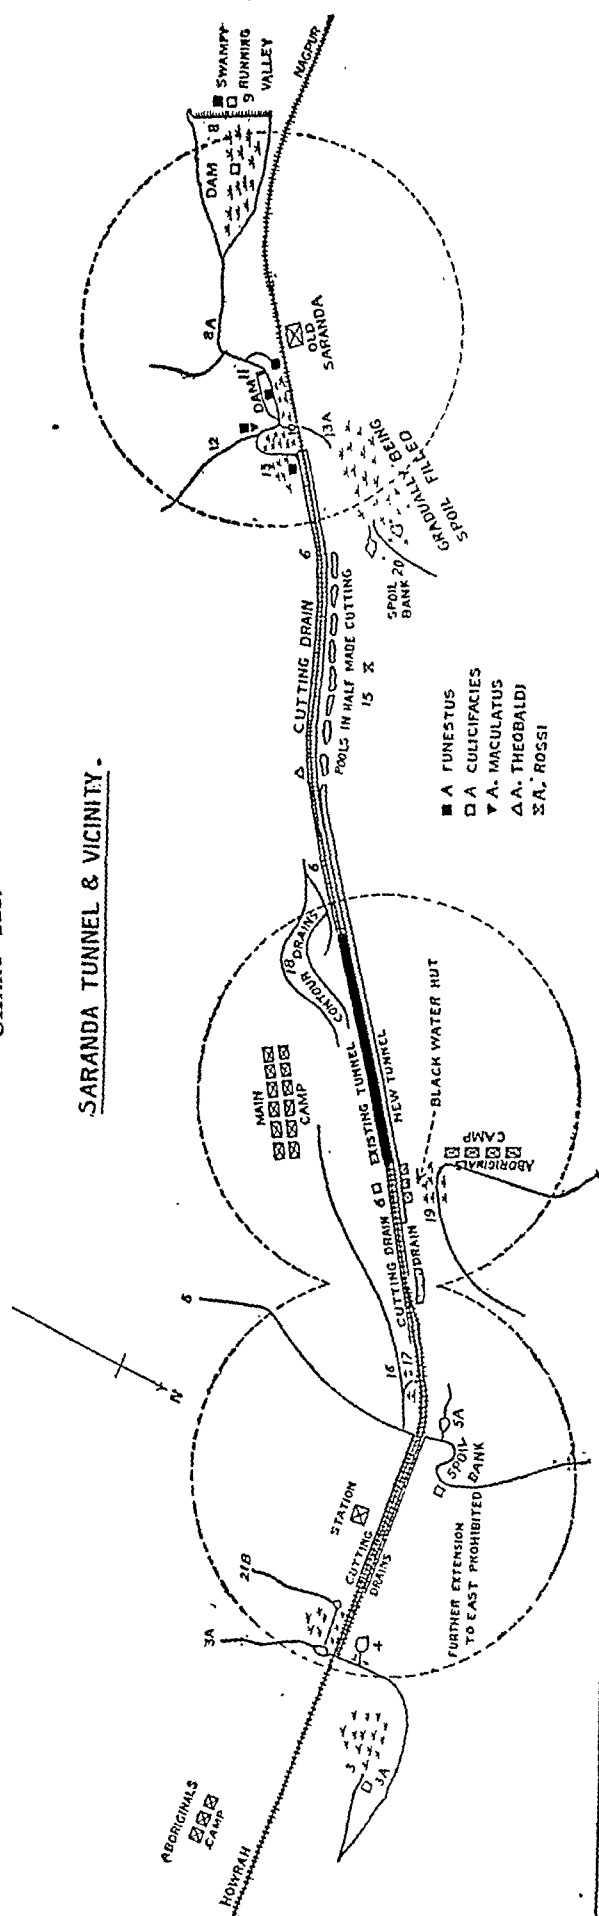

Of those affecting the main camp, Nos. 6 and 16 are the same as have just been referred to; No. 19 swamp had a drain put through it; and the hill side contour drains, (No. 18), which had been put in years back to keep the rush of water off the hillside from falling in sheets on to the track over the edge of the cutting at the west end of the tunnel, were thoroughly cleaned of bush and their floors made, as far as possible, of even slope. As they can now be walked along without difficulty, it is easy to see the few places where seepage springs arise in them, and treat the same with oil.

in great numbers, with (No. 9), a swampy valley between high hills extending below it parallel to the line for nearly a mile. This dam and valley were not on railway land, and the drainage of the latter was rendered impossible by the fact that the outflow passed through an arch under the line on high embankment, the floor of which was level with the top of the swamp. To put in a central and bank foot contour drains to dry out the valley and concentrate the water for oiling if necessary would be useless since the level of the floor of the arch did not permit of an outflow for the drains.

It is this valley, a mass of *A. funestus* breeding, which doubtless made the former station here so unhealthy. In consultation with the District Engineer and the contractors therefore, it was decided to permit only aboriginals to reside in the camp here. As a matter of fact, few such were living there at the time of the survey, and they appeared quite reasonably healthy. Very significant, however, was the abandoned camp of a gang of Bengal Mohammedans, close to the huts of the aboriginals, who had bolted on account of malaria.

CHART III.

SARANDA TUNNEL & VICINITY.

On account of the prevailing wind, control was taken down to breeding place 13, nearly three-quarters of a mile from the centre of the main camp. Owing to the amount of wild animals in these forests, the ordinary sanitary inspector class absolutely refused to enter them, and here again it was necessary to appoint an ex-sergeant of the British Army as Inspector. The results are given in Table VII, and show how the disease was almost immediately got under control. There was a steady decrease in incidence every month from August to November, in which period one might well have expected some signs of the autumn apex to appear. In November and December, when I was satisfied that all breeding was under control, 10 grains of quinine on the weekly market day were given to all who would take it, and by Christmas the only sufferers from malaria were a few persons who had persistently refused quinine.

TABLE VII.

Monthly Malaria Percentage, Saranda Tunnel Works.

	January.	February.	March.	April.	May.	June.	July.	August.	September.	October.	November.	December.
1925	21.5	20.3	18.3	?	?	?
1926	?	8.8	7.2	4.1	6.0	6.2	5.7	4.1	2.9	2.8	2.4	2.4

The original cost of the survey and preliminary drainage works, including salaries, was in the neighbourhood of Rs. 3,000; thereafter maintenance, including salaries and oil, has averaged Rs. 92 per week, but the inspector has time on his hands for attendance on other stations, and when these are taken up and part of his salary allotted to them, the cost will fall to Rs. 39 weekly. For this trifling amount one of the most notoriously deadly spots in the whole of Singhbhum has been rendered practically malaria free.

APPENDIX I.

Notes on a case of Blackwater Fever at Saranda Tunnel Works, July 1926.

Child, male. Aged 5 years. From Rewa State. Residence at Saranda, over twelve months.

History.—Malaria on and off for a year. Quinine taken irregularly. Three days before onset of blackwater an attack of malaria. For forty-eight hours prior to attack gr. iv quinine sulph. in solution once daily.

Attack.—Dark urine noticed by parents 9 p.m. Total suppression of urine for twelve hours thereafter. Then seen by Assistant Surgeon. Grain ii (half an ampoule) caffeine sodii. benzoate intramuscularly. Within a few minutes of injection passed 10 oz. coffee coloured urine with heavy black deposit thrown down at once.

Temp. immediately after passing urine 103°F. Pulse 158.

In half an hour, further desire to micturate. Passed 2 or 3 c.c. only of tea coloured urine.

Restless. Abdomen very tympanitic. Soap enema, (child struggled wildly). A large *Ascaris* voided, but little faecal matter.

In afternoon another half ampoule of caffeine sodii. benzoate.

Death about 9 p.m. (twenty-four hours from onset of attack). Apparently due to heart failure. Post-mortem refused.

Parasite findings, thin film, taken 9 a.m. (12 hours after onset).

	Rings.	'Tenue Tropho- forms.'	Schi- zoites.	Gameto- zontes.	Per cytes.	cent.
M. T. .. 21	7					26.7
B. T. .. 24		44	3	6		73.3

Very noticeable were—

- (1) The large number of enlarged R. B. Cs. with no contained parasites, as if these had been washed off them.
- (2) Polymorphonuclears containing large blocks of ♀ round pigment such as is commonly seen in crescents. (Note: no M. T. gametocytes).
- (3) All parasites of both species undergoing plasmodysis and karyorrhexis, cytoplasm more degenerate than nuclei. Owing to the more delicate nature of the M. T. parasite this may make the count of the latter too low, but error is probably balanced by the empty enlarged R. B. Cs. which had certainly contained B. T. parasites.

The lysin acting on the blood seems to have been a lysin for the malaria parasites also. R. B. Cs. containing degenerating parasites were themselves in good condition, (achromia, of course, excepted).

The predominant infection in this case was certainly B. T.

II.

Malaria on the Open Line.

In the previous section conditions were dealt with under which very strict adherence to railway-owned land is not essential. Out in the wilds this is seldom so. In any case the average landholder will stretch a point if he understands the object is the control of *bokhar*. On the Raipur-Vizianagram Railway, for instance, 'non-interference with irrigation' was the only stipulation of Government in respect of power to go beyond the acquired land for anti-malaria purposes; at Saranda tunnel the Forest Department freely gave permission for the clearing of undergrowth and young trees for the short distance each side of a stream required for training and oiling the latter, but on the open line settled conditions and vested interests are encountered, especially around stations, (where alone anti-malaria work is usually required), which do really reduce the area on which anti-larval measures can be undertaken almost to the Euclidian straight line, but it is hoped that the accounts which follow of various works on the open line will show that even with this apparently insuperable obstacle enormous improvements can be affected.

1. *The Effect on a Division Terminal of Malarious Wayside Stations.*—Chakradharpur, in Chota Nagpur, 195 miles from Calcutta, is an engine-changing station and marshalling yard. The eastward run is to Kharagpur, 72 miles from Howrah, across fairly level country. The westward run is to Jharsuguda, on the boundary of Orissa and the Central Provinces, 125 miles, the route involving the crossing of the range at Saranda, the rest of the run being through heavily forested country, rich in mineral wealth besides, in which a heavy traffic originates. A further run from Chakradharpur is north-eastward to Adra in the Coalfields district.

Chakradharpur has a bad reputation for malaria among subordinates, though it is noteworthy that officers stationed there suffer little. It might easily be supposed that proper use of nets by the latter is the explanatory cause, but that this is not so will be shown.

In Table VIII the percentage malaria incidence among the staff and their dependants is given for one and three-quarter years, divided in respect of whether their duties take them on the line beyond station limits, (running staff, train crews), or confine them to the station and yards, (stationary staff). It will be seen that the incidence of malaria among

the running staff for 1925 is exactly twenty times as heavy as on the stationary staff, whilst an attack on a 'running' man results in thrice as long an incapacitation as on a 'stationary' man. In other words, the virulence of an attack on the former class is three times as great. As will be seen later, the

probable reason for this is that running staff attacks are largely matters of fresh infection, stationary, occasional relapses of old standing malaria.

It is of course arguable that the running staff's duties expose them far more to illness of all kinds, on account of the irregular hours and exposure their duties entail, but night work in the open in all weathers faces equally the yard employé, and I do not think the argument is sound. The real reason is that the duties of the running staff take them into places where they are constantly exposed to fresh infections of malaria.

Study of the Chakradharpur records showed that in every case of running staff reporting sick with malaria, there was an immediately previous history of night work on the west bound run. It would be tedious to give full instances; extracts from a month's records will suffice, confined entirely to cases where the previous and immediately subsequent duties of the men concerned render the locality and date of infection practically certain.* The agreement between the period elapsing between the presumed 'infective' run and the onset of the attack is too closely in agreement with the regular incubation period of malarial infection to be fortuitous, and I submit can be taken as proving that the runs tabulated were responsible for the ensuing attacks.

* Not re-published.

Absolute proof that Chakradharpur itself is not, and that the stations to the west emphatically are, malarious is furnished by the child spleen rates of the stations, and their adjacent villages, where present, on the fifty-three miles to Bisra, across the Saranda range. The writer's time on the railway terminating sooner than was expected, did not permit of the completion of the spleen rates up to Jharsuguda, but there are some notoriously malarious stations between Bisra and that place.

It is sometimes maintained that it is hopeless to try and deal with malaria at wayside stations. The cost would be out of all proportion to the number of staff benefited. On the face of it this may be so, but when it is realised that these small stations, as in the instance of this division, are responsible for far more malaria than occurs among their own limited staffs, the matter assumes a different aspect. Moreover, as pointed out to the writer by the Chief Medical Officer of the Eastern Bengal Railway, malaria

falls especially heavily on the small station, the absence of a man off duty is more felt and occasions greater disorganisation—may be in main line train-working—than at larger stations, whilst relief is less easily obtainable.

In a length such as that under consideration, little or no benefits to the division point would accrue from clearing up one station, the whole sub-section from Goilkera to Manharpur at least would require taking up before any improvement would be seen. That this would be financially justifiable the account of what can be achieved at one station I think proves.

In regard to the problem of cleaning up the section Goilkera-Manharpur, very little interference with other than railway land is required, as per the following brief notes on the breeding places affecting each station:—*Goilkera*. The malaria arises from a stream crossing the railway east of the station, into which systems of borrow pits each side of the line drain, and from a swamp south-west of the station in which there are springs and *A. funestus*. Canalization of the stream from its head in several small ravines in the forest south-east of the station and the proper draining into it of the borrow pits, so that the whole can be oiled, is quite a simple matter. The swamp, which is the chief source of malaria affecting the down trains which stand for some time detaching their bank engines, and the returning bank engines waiting to enter on the single line section down to Manharpur, is likewise susceptible to drainage and oiling, or to subsoil drainage, though great improvement could be affected merely by putting it back under rice within the railway boundary.

Saranda.—Dealt with, as regards the station, in Part I of this paper. *New Block Post*, Mile 220. Until the culvert referred to in the description of old Saranda, which is almost directly beneath the site of this, is lowered, nothing can be done to ameliorate conditions here. Consequently one is driven back on to mosquito proofing the signal box *cum* living quarters, as on the Italian State Railways through the Roman campagna.

Posoita.—The badly connected borrow pits on each side of the station account for nearly all the malaria, causing the extraordinarily high spleen rate. Beyond that a little stream training and the improvement on the same lines of an irrigation channel in the rice field north of the station are all that is required.

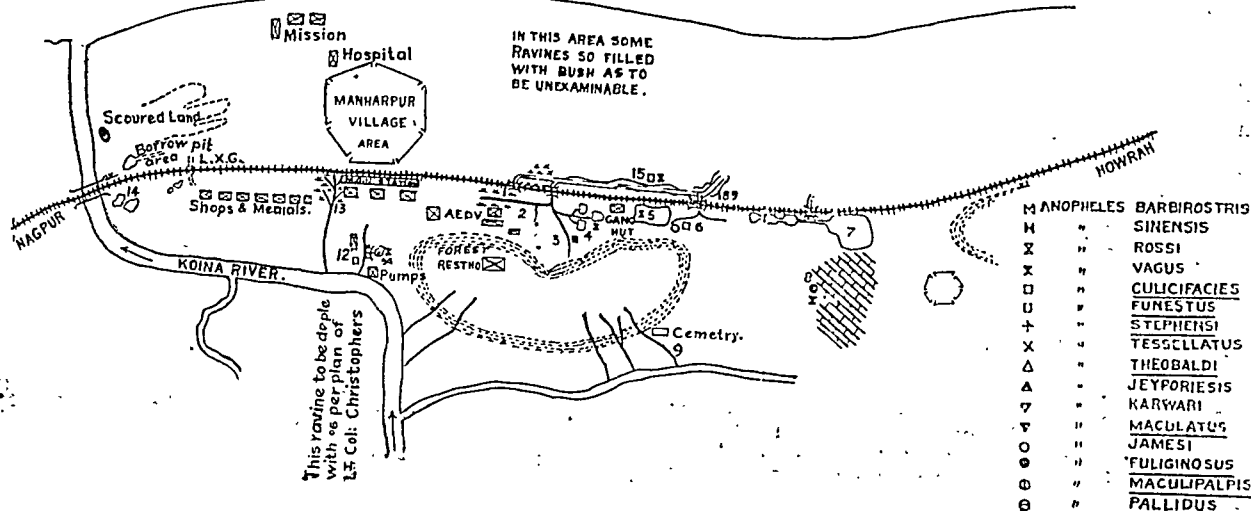

Manharpur.—The plan of the breeding places here, (Chart IV), should be consulted in apposition to the

CHART IV.

MANHARPUR STATION.

NOT TO SCALE.

S. KOEL RIVER.

plan in Christophers (1925). The work is simple. Owing to the bank engines stationed here this place is of greater importance than the remaining stations on this length.

Jaraikela.—The problem is almost identical with Posoita. The whole trouble arises from a series of badly connected borrow pits. Engineering plans in connection with further doubling contemplate the removal of this source of nuisance by a straight drain suitable from an anti-malaria point of view, easily oilable. Thus in this case anti-malaria operations are not properly chargeable with the work, though until doubling is carried out they may have to bear the cost.

The foregoing examples are instances, which every railway medical officer will be able to duplicate from his own experiences, in which railways are seen to be largely responsible for their own malaria. In the words of Sir Malcolm Watson, it is high time that engineers realized that "work which, without excuse, leaves a trail of malaria behind it is bad engineering." A most perfect example of this is considered in detail in the next section. There is no doubt that until an engineer's training teaches him to avoid creating breeding places in the course of his operations, medical departments will have to maintain a malariologist to prevent engineer-created ill health, and in any case to clean up behind the happenings of past years.

Apart from the capital cost, unestimated for, breeding could be controlled on the section Goilkera-Manharpur for about Rs. 600 monthly.

III.

A Malaria Campaign at an Open-Line Station.

At Amda Junction, in the Singbhum District, 182 miles from Howrah, a branch leaves the main line for the rich iron-ore district in the hills to the south. Forty-seven miles up this branch lies Dangoaposi, its local headquarters. Above this point the iron mines are served by several small branches and the grades become very heavy, so that full loads cannot be made up until the ore-waggons which form the bulk of the traffic have been marshalled into train loads at Dangoaposi, where there is therefore stationed a considerable locomotive and shunting staff.

The difficulties encountered during the construction of this branch, known as the 'Amda-Jamda' have been mentioned previously, and Dangoaposi was chosen as the local headquarters in preference to Noamundi, the succeeding station, as it had proved much more healthy than the latter during construction. The line was handed over for traffic early in 1925, but the local dispensary on open line schedule was not opened until March of that year, and hence no records are available for the first three months.

NOTES:—No figures available for January—March 1925. Anti-malaria measures taken from November 1925, p. m. = per mensem. p. a. = per annum. Total population of Railway Colony averages 220, composed of: Stationary Staff 72; Running Staff 14 (on average traffic); Dependants 134.

It will thus be seen that the locomotive department quarters at the east end of the yard were close to breeding places 3, 23, and 29, of which the first and last also affected the blocks of menials' quarters behind the loco. shed, but the main trouble was the interference caused by engineering works that had resulted in creating the system of running drains with swampy margins extending from No. 31 on the east to No. 14 on the west, and the two are as of shallow pools, Nos. 12 and 13, formed by seepage springs at the foot of cuttings.

Outside railway land no dangerous breeding was found, save in a small piece of rice field adjacent to breeding place No. 3, but the rice fields were full of *A. sinensis*. I have never encountered this common species in such profusion elsewhere.

Collections of adults in the quarters yielded the following species, most of the specimens being engorged:—

Locomotive Department, 6 blocks—

<i>A. sinensis</i>	27	56%
<i>A. barbirostris</i>	7	15%
<i>A. pallidus</i>	5	11%
<i>A. rossi</i>	3	6%
<i>A. fuliginosus</i>	2	4%
<i>A. culicifacies</i>	2	4%
<i>A. funestus</i>	2	4%
			48	

Traffic Department, 3 blocks—

<i>A. sinensis</i>	5	55%
<i>A. fuliginosus</i>	4	45%

Engineering Department, P. W. I. bungalow, 2 blocks—

<i>A. fuliginosus</i>	6	75%
<i>A. pallidus</i>	2	25%

The two engorged *funestus*, with mature eggs, indicating that the feed was at least their second, proved negative for parasites.

Ordinary mosquito nuisance was very great. The principal species were *Culex biteniorhynchus* and one of the *vishnui*-group. One *Stegomyia albopicta* was taken in the P. W. I.'s bungalow.

Before any regular preventive measures could be attempted it was necessary to combat the existing outbreak and get the station working again. As the campaign is not without its instructive side, it is next described.

The running drains were oiled without training by soaked swabs, which did away with a large proportion of the larvæ, whilst the seepage pools Nos. 12 and 13 were roughly drained out as far as possible, and the residual water oiled by hand sprinkling from a bucket. These pools were, when found, literally black round their margins with *culicifacies* larvæ.

Having thus cut off the main supply of anophelines, measures were taken to deal with those already in the adult state and to control the developed disease. For the former, all that could be done, but it was very effective, was to cut down the monsoon growth of shrubs, (mainly *Crotolaria*), which covered the land around the quarters to a height of two to three feet. This abolished the chief day-time resting place of the anophelines. Those already in the houses and presumably infected to a considerable extent, could not be touched with the apparatus and staff available. There were far too many sick in the quarters to contemplate evacuation and fumigation.

For the second, regular medication of everyone was attempted, and this brought out some interesting points.

Prior to my arrival on the scene of the epidemic, the medical officer of the district had of course paid as many visits as the other calls on his time permitted of. Grains xv. quinine sulphate in solution twice weekly had been ordered, subsequently changed to gr. x at more frequent intervals. This was supposed to be being dealt round to everyone by the sub-assistant surgeon and his compounder. Investigation of the dispensary books showed that on the quinine consumption therein recorded, no more than thirty-six doses per diem had been issued among a population of over two hundred during the previous six weeks. Like most of his class, the sub-assistant surgeon, unable to get the people for treatment at his dispensary without much trouble, had failed to organize a *bandobast* for reaching them with his medicines.

In the first place, a complete census by name and house of all in the station had to be drawn up. This being done, a check was available. I do not think that prior to this being made, anyone realized nearly how many persons there were in the settlement. Thereupon medication was started with the following mixture, prescribed by the Acting Chief Medical Officer:—

<i>Cinchona febrifuge</i>	gr. x.
<i>Acid citrici</i>	gr. xx.
<i>Mag. sulph.</i>	gr. xx.
<i>Spt. anisi</i>	m. x.
<i>Syr. simplex.</i>	m. x.x.

Aq. ad to 1 oz.

This was sent up in bottles from the Medical Stores to obviate further work on the spot, as the compounder was the victim of frequent attacks, though never failing to revert to duty as soon after as he was able.

Naturally an officer has many advantages over a subordinate in attempting to organize anything affecting more than one department. With my assistant, an assistant surgeon, there were thus three of the Medical Department on the spot. At my instance the local heads of other departments, the Traffic Inspector, (acting for the Station-master, in hospital), the Loco. Foreman and the Permanent Way Inspector were summoned and on the first evening after the arrival of the febrifuge mixture an attempt was made to administer a dose to all in the settlement. The work took two and a half hours after the close of the day's normal duties for all of them, extending to long after dark, but in this time only 143 doses were given. The remainder of the population could not be found or were out on the line. No opposition was encountered at the time, but on the following morning there was a general complaint of vomiting and excessive purgation. *Mag. sulph.* in the mixture was cut down to gr. x. in subsequent consignments. In any case there is no doubt that the mixture was given at an unsuitable hour, when most of the inhabitants were cooking, or had just consumed their evening meal. It was manifestly impossible to wait for two hours after all had eaten, as by then the majority would then have been fast asleep.

The next two nights I attempted to get everyone except *purdah* women together at the hospital, leaving the latter for the sub-assistant surgeon to deal with by house-to-house visiting. Even after long delays whilst absentees, who had been seen by some one or other, were sent for, the medication roll was incomplete when checked against the census. Finally, to give the dose at a more suitable time, well before a meal, special orders were issued. Thereafter it is estimated that about 90 per cent. of the inhabitants were reached daily. Short of absolute military discipline I doubt if better results are obtainable. Epidemics of this nature emphatically require a medical officer in charge, yet what

railway medical department has an officer available to give his whole time to such? An epidemic in one place is invariably associated with a general exacerbation of the disease all over a district, and the M. O. thereof cannot possibly devote his whole time even to the place worst affected. Hence the inordinate delay in getting the traffic moving again which characterises these outbreaks when they affect important centres. Within the last three years at least three of the largest railways in this country have experienced similar outbreaks, all of them on a large scale, affecting more important division points than the one here described.

The permanent anti-malaria scheme is shown in Chart V. This was carried out in the first six months of 1926, to be ready for the subsequent monsoon. Its results are apparent from a study of Table X. The success achieved was most striking, for malaria almost ceased to exist at Dangoaposi. It is of course highly probable that in any case the following year would not have shown such extremely high incidence as 1926,—though the way in which *culicifacies* started to breed in one place where the first week's oiling after the onset of the rains was omitted makes this not too certain.

Up to the time when the writer left the railway the capital cost of the scheme was not available, and in any case the works carried out included many points, such as the final tidying up of the yard and ash filling instead of draining swamps to make a recreation ground, which are not properly chargeable to malaria works. The original estimate was about Rs. 18,000, being the capitalized 1925 loss on sick pay alone, at eight years' purchase, but this included subsoil piping breeding place No. 12, which was not done owing to the layout of the yard being incomplete and liable to change, and the engineers very rightly not wanting to have tracks on the top of a pipe line which might want lifting and relaying, so its place was taken by an open drains system and oiling, at least *pro. tem.* Probably half of the above sum is actually debitable to anti-malaria operations direct. In addition, the upkeep charge in 1926 averaged Rs. 28 weekly for 23 weeks until the various waters dried up just before Christmas, or Rs. 624 in all. I think the reduction amply justifies the outlay and proves the financial as well as the scientific practicability of control at stations on open lines.

There is no doubt that the remaining three stations to the terminus at Gua are entirely responsible for this, as there is little malaria at stations lower down the branch or at Amda Junction, the hooking-off place on the northward runs. Malaria will not disappear from Dangoaposi until Noamundi, Jamda and Gua and the end points of the various ore branches are dealt with, and will assume an increasingly serious aspect as regards the running staff as traffic develops. An interesting point thus brought out is the greater virulence of these attacks, mainly fresh infections, compared with the occasional relapses of the stationary staff.* For example, attack cost a running man 5.5 days' absence in October 1926, as compared with 0.25 days for a relapse in a stationary man. The virulence of these presumably fresh infections was thus twenty-two times greater than a relapse, as measured by their incapacitating effect.

III.

The Importance of Borrow Pits.

On page 61 it was stated that these, when freshly excavated, bred only *A. rossi* and *A. vagus*, according to locality. It now remains to consider what part they play in malaria causation when old and full of vegetation, as is their general condition on the open line.

The ordinary borrow pit contains standing water. It is exceptional to find them connected for drainage purposes. When this has been done, and badly done, as appears to be the inevitable rule, they really become pools in a stream, and, as left by the engineers are definitely dangerous, producing mainly *A. funestus*.

Standing water borrow pits, even when there was no possible chance of seepage springs altering their usual character, I have found to contain the following species:—

A. barbirostris.
A. sinensis.
A. culicifacies.
A. funestus.
A. rossi.
A. vagus.
A. fuliginosus.
A. pallidus.

The third and fourth on the list are definitely dangerous malaria carriers.

The oiling and maintenance was placed under the sub-assistant surgeon, who had a special gang of six coolies during the rains for this and keeping jungle growth down. Occasional visits were paid by the European sanitary inspector stationed at Saranda tunnel works.

Table XIII gives the spleen rates in detail during the 1925 epidemic and a year subsequently. The figures are eloquent of the improvement.

The figures in Table X shows that the running staff are still contracting malaria, another instance of the point made in the preceding section of the importance of dealing with small stations.

There is as yet an unexplained sporadicity in regard to the appearance of *A. funestus* in borrow pits of the ordinary type. It is only occasionally that one finds this species, and it is then invariably associated with

* Very few transfers to and from Dangoaposi occurred during the year 1926. Such as occurred were mainly among drivers, which further proves my point. One or two regular cases of malaria among the stationary staff were traced to aboriginal (Ho) members of the staff living in villages near the station but beyond the protected area. Quarters being available, these men were forced to live in them.

very clear water, but that of itself tells nothing. In railway malaria work, when borrow pits exist within the 'warning' signal at each end of a station, they should be kept marginally clear of all vegetation, and only line fishing, not netting, permitted in them. If possible, they should be filled up. At any station with a water column, fire cleaning results in a gradual accumulation of ashes that are usually available for the slow but almost costless carrying out of this work. If ashes are dumped into pits daily, poisonous substances seem to leach out of them which have an inhibitory effect on breeding.

APPENDIX IV.

The Position of A. fuliginosus as a Carrier.

Though this species is a proved malaria carrier in Nature, it appears to have little or no practical importance in this respect.

An instance when it was neglected with complete success is given in respect of Artham Base Camp, (Chart II), in the first section of this paper. Likewise it was not attacked in tank No. 11 at Dangoaposi, (Chart V), again without ill results. At Santragachi, the B. N. Railway Locomotive and Carriage sheds five miles from Howrah, though there is a certain amount of malaria, this species does not appear in numbers until after the annual peak of the curve is well on the down grade. In January 1926 it formed 93 per cent. of all anophelines taken in the quarters at this station, and yet malaria incidence at the time was as low as it ever is there.

A probable explanation is that, being a species with winter maximum, temperature factors are unfavourable to sporozoite development, but this hypothesis hardly suffices in the Northern Circars, for instance, and it would appear probable that the susceptibility to infection is extremely low. Work on this point is urgently required. If this species has any practical importance, then mosquito malaria control in Bengal becomes a virtual impossibility, but all the available evidence, as stated above, is the other way.

In conclusion I wish to express my thanks to my former Assistant, Assistant Surgeon Adhikari of the B. N. Railway, who is responsible for a large proportion of the spleen rates included in this paper, and to Assistant Surgeon Chowdhury, B. N. Railway, in medical charge of District I of the Raipur-Vizianagram Construction, for keeping up the study of blood films in his district at times when the writer and his assistant were absent elsewhere.

A SIMPLIFIED METHOD FOR ESTIMATION OF SUGAR IN THE BLOOD.

By J. P. BOSE, M.B., F.C.S. (Lond.),

Diabetes Research Worker.

Calcutta School of Tropical Medicine and Hygiene.

(Dr. A. Mitra Research Scholarship).

(Demonstrated at the Scientific Exhibition of the 7th Congress of the Far Eastern Association of Tropical Medicine).

(December 1927).

THAT normal blood contains sugar has been known from the time of Claude Bernard, and since then numerous methods have been devised by workers all over the world for estimating its amount, many of these being obsolete now. Formerly, the estimation of sugar in blood used to be a tedious procedure; but nowadays it is a much more simple process. But even so, nearly all the methods for blood-sugar estimation require a well-fitted laboratory and a fairly well-trained worker to carry out the test.

The importance of blood-sugar has increased enormously since the insulin treatment has come into use. All cases of diabetes undergoing insulin treatment require periodical, sometimes daily examination of the blood-sugar. In large cities like Calcutta, with well-equipped hospitals and laboratories with trained workers in them, this is possible; but what about the distant mofussil towns and villages, in some of which places even a qualified medical man is often wanting?

A doctor in such a place is very much handicapped in treating a case of diabetes with insulin, not being able to get any idea of what the initial blood-sugar level is and also what changes take place in the blood-sugar during insulin treatment. It has been suggested that where blood-sugar estimation is not possible, insulin treatment can be carried on by relying on the urinary sugar only. To my mind, this appears to be an unsound and sometimes a dangerous procedure. I have seen a few cases of renal glycosuria treated with insulin, with results just short of a disaster. Even in a case of diabetes, one does not get a clear indication about the proper dose of insulin to be injected and also about the interval of time between injections, without a knowledge of the patient's blood-sugar, and this is essential for the successful treatment of diabetes mellitus. To give too small a dose of insulin and at too long intervals will not do much good to the patient, and to give an overdose of insulin, on the other hand, may mean disaster.

We know that the urine may become sugar-free but the blood-sugar may still be 50 per cent. higher than normal. Insulin injections are usually stopped at this stage for fear of inducing hypo-glycæmia by those who take the urinary sugar as the only guide; but the blood still being in the hyper-glycæmic state, the pancreas does not get sufficient rest, and so the ultimate results of such treatment are often unsatisfactory. The fundamental principle of treatment of all cases of diabetes is to take as much strain from the

pancreas as practicable and this is only possible when the blood-sugar is kept at a normal level. In my opinion, the insulin treatment of diabetes ought not to be done without regular blood-sugar tests being made, unless of course the case is one of urgency, and this too must be done very cautiously.

In order to help practitioners in mofussil towns and villages to successfully carry out insulin treatment by regular blood-sugar tests, I have been trying for some time past to devise a simplified method for the estimation of the sugar content of blood, which will be fairly accurate for clinical purposes and at the same time easy and quick for the busy practitioners to carry out the test. Such a test has now been devised, and controls by authenticated blood-sugar methods show the results are accurate up to the second place of decimals. A detailed description of the method is given below.

Author's Simplified method for blood-sugar estimation.

Apparatus required:—(in detail).

One test-tube rack.
One glass tube, for oxalated blood (method given in detail).

A few test-tubes.—Size 4 in. \times $\frac{1}{2}$ in. for collecting oxalated blood.

A few extraction tubes, size 2 in \times $\frac{3}{4}$ in. for extracting blood in distilled water.

One 10 c.c. pipette divided into 1|10ths, for measuring distilled water.

One 1 c.c. pipette divided into 1|100ths, for measuring blood.

Two 1 c.c. pipettes divided into 1|10ths, for measuring out the two precipitating reagents.

Small glass rods for stirring up the blood after precipitation.

Small funnels. For filtration of blood after precipitation.

Filter paper (Ordinary—5.5 cm.)

Two 1 c.c. pipettes with one mark only. One for making the diluted standard glucose, and the other for measuring out diluted standard glucose for experiments.

One 50 c.c. measuring flask, for making standard glucose.

Two special 30 c.c. graduated tubes, for boiling the blood filtrate and the glucose control with copper solution.

Three 2 c.c. pipettes with 1 mark only—Two for measuring out the copper solution and the phosphomolybdic acid, and one for measuring out the blood filtrate.

Copper water bath for boiling.

Spirit lamp.

Comparator.

Reagents:—

Powdered potassium oxalate (neutral).

Sodium tungstate (pure cryst.)—10 per cent. solution.

Acid sulphuric—2|3 N.

Grape sugar tablets. (Merck)—each 0.25 gm., making stock standard glucose solution.

Toluol—for preserving the stock standard glucose solution.

Alkaline copper solution.

Phosphomolybdic acid.

Distilled water.

The Alkaline Copper solution is made up as follows:

Sodium Carbonate (anhydrous) .. 40 gms.

Acid Tartaric (Pure) .. 7.5 gms.

Copper Sulphate (Pure cryst) .. 4.5 gms.

The sodium carbonate is dissolved in about 400 c.c. of distilled water in a litre flask; warming of the solution on a water bath may be necessary. The copper sulphate is dissolved separately and added to the carbonate solution with shaking. Finally, the tartaric acid is dissolved in a separate beaker and added to the flask. The receptacles in which the copper sulphate and the tartaric acid are dissolved must be repeatedly washed with distilled water and the washings added to the flask. When cool, distilled water should be added and the solution made up to a litre. It should then be filtered if necessary and bottled.

Phosphomolybdic Acid Solution:—

Acid molybdic (Pure—free from ammonia) 35 gms.

Acid phosphoric (Pure—85 per cent.) .. 125 c.c.

Sodium hydroxide (Pure—10 per cent. solution) 200

c.c.

Dissolve 35 grammes of pure molybdic acid in 200 c.c. of 10 per cent. sodium hydroxide solution and add 200 c.c. of distilled water. Boil until all traces of ammonia are driven off. (This can be tested by presenting a glass rod dipped in pure hydrochloride acid); cool, and add 125 c.c. of phosphoric acid (85 per cent.) When sufficiently cold, make up to 500 c.c. with distilled water.

(N.B.—This solution should be of such a strength that 2 c.c. of this will completely discharge the blue colour from 2 c.c. of the alkaline copper solution. It is advisable to test these reagents occasionally and to make blank experiments with them from time to time.)

Stock solution of glucose 1 per cent.

The stock solution of glucose can be conveniently made up by taking two glucose tablets, each 0.25 gm., and dissolving these in 50 c.c. of distilled water in the 50 c.c. flask. This is bottled and preserved with a few drops of toluol, which should form a thin layer on the surface of the solution. This stock solution should be checked now and then as regards the sugar content by Fehling's or Benedict's method.

Diluted glucose solution:—

To make the diluted standard for experiment, take 1 c.c. of the stock solution in a 1 c.c. pipette and make it up to 50 c.c. with distilled water in the measuring flask, which must be washed clean with distilled water. This should be made up fresh every time.

1 c.c. of this diluted standard solution contains 0.2 mgm. of glucose.

Method of estimation.

With the usual aseptic precautions, draw $\frac{1}{2}$ to 1 c.c. of blood from the vein of the patient. With a little practice, this small amount of blood can also be collected from a deep finger prick. For this the patient should be instructed to dip the hand in hot water and after thorough drying, to swing the arm vigorously, backwards and forwards for a little time. A thin rubber tubing is then wound round the finger tightly, and after sterilizing with ether, the portion of the finger just below the bed of the nail is then smartly jabbed with a sterilized sharp surgical needle. By squeezing the finger 0.5 c.c. of blood can easily be obtained. Collect the blood directly into an oxalated tube.*

In an extraction tube measure out 3 c.c. of distilled water by means of the graduated 10 c.c. pipette. Accurately measure out 0.2 c.c. of blood by means of the finely graduated 1 c.c. pipette.

* The easiest way of preparing an oxalated tube is to blow inside the test tube with a glass tube and then to sprinkle some finely powdered neutral potassium oxalate inside. The inner walls of the tube thus becoming moist through blowing; the oxalate will stick to the sides in a uniform layer.

(divided 1/100ths) and deliver it into the extraction tube. Shake lightly and wait till all the corpuscles become laked and the solution becomes clear red (Plate I A).

Now add 0.4 c.c. of 10 per cent. sodium tungstate solution, followed immediately by 0.4 c.c. of 2/3 N sulphuric acid, by means of the two ordinary graduated 1 c.c. pipettes (divided 1/10ths) and stir with a glass rod. The addition of sodium tungstate and sulphuric acid precipitates the protein and the colouring matter of the blood. The precipitate is reddish at first, but soon turns viscous and becomes of a greyish brown colour (Plate I B).

When the precipitation is complete, the solution is filtered through a small filter paper. The filtrate obtained should be crystal clear. For the estimation, measure out 2 c.c. of the clear filtrate into the special graduated 30 c.c. tube by means of a 2 c.c. pipette. Mark this tube with "U" (unknown). Into another 30 c.c. graduated tube take 1 c.c. of the *diluted standard glucose solution* by means of another 1 c.c. pipette with one mark, and add 1 c.c. of distilled water to it. Mark this as "S" (standard). Now add 2 c.c. of the alkaline copper solution to each of these two tubes by means of a 2 c.c. pipette. Shake the two tubes by gently stroking the bottom of the tubes against the palm of the hand.

The two tubes are now introduced into the copper bath in which water is already boiling and allowed to remain there for 10 minutes. They are then removed from the bath, and the contents will be found to be of bluish solution with a reddish brown precipitate of cuprous oxide at the bottom of the tube: 2 c.c. of phosphomolybdic acid solution are then immediately added to each of the two tubes by means of a 2 c.c. pipette. A brisk effervescence occurs and the solutions in the two tubes turn deep blue. (Plates I, C & D). Phosphomolybdic acid, as has already been stated, discharges the blue colour of *unreduced* copper solution; but here it will deepen the colour by combining with the *reduced* copper oxide. The intensity of the blue colour developed is directly proportional to the amount of reduced copper present, which again is dependent on the amount of the sugar present. Shake the two tubes by slightly inclining the tubes and tapping the bottom against the palm of the hand.

Now put these two tubes inside the "Comparator" (Fig. I), and add distilled water very carefully to the tube having a deeper colour—either the 'standard' or the 'unknown,' in whichever tube the colour of the solution is deeper. Dilution with water is carried on until the two solutions are matched in colour exactly. (Plates I, E & F). After addition of distilled water each time mix the contents thoroughly by putting in the cork and inverting the tube.

Calculation.

It has already been mentioned that the intensity of the blue colour after addition of phosphomolybdic acid depends on the amount of the

reduced copper present, which in its turn is proportional to the amount of sugar present in the two tubes.

Now when the solutions in the two tubes are exactly matched in colour, it may be assumed that the concentration of sugar in both of them is the same, but the quantity of sugar present in each will vary in direct proportion to the respective volumes of the solutions. In the present case the solution in the tube marked "S" is known to contain 0.2 mgm., of sugar, and from this data, the amount of sugar in the other is easily found out by calculation.

Let us take a concrete example. Let us suppose that the solution in the "standard" tube is deeper in colour and had to be diluted up to 12 c.c. to match exactly in colour with the 6 c.c. of the solution in the unknown tube. Here although the concentration of sugar in the two solutions is the same, the quantity of sugar present in the standard tube is double what is present in the "unknown" tube, the quantity being directly proportional to the volumes of the solutions contained in the two tubes.

We know that the 12 c.c. of the solution in the "standard" tube contains 0.2 mgm. of glucose. Therefore, the sugar content of the 6 c.c. of the solution in the 'unknown' is half, i.e., 0.1 mgm.

The proportional contents of the sugar in the unknown solution is thus readily calculated by simple rule of three.

Standard.	Unknown.	Strength of glucose.
12 c.c. :	6 c.c. ::	0.2 mgm. : x
$\therefore x = \frac{6 \times 0.2 \text{ mgm.}}{12} = 0.100 \text{ mgm.}$		

Now it will be remembered that originally 0.2 c.c. of blood was taken for experiment and was made up to a total volume of 4 c.c.; after filtration, only 2 c.c. were taken for estimation. Therefore, the quantity of blood actually taken for experiment was 0.1 c.c.

Now if 0.1 c.c. of blood contains 0.1 mgm. of sugar, 100 c.c. of blood will contain 100 mgm. which is equivalent to 0.100 gram (per cent.).

Now supposing that the solution in the "unknown" tube is deeper in colour and has to be diluted to 8 c.c. to match in colour with the solution in the "standard" tube. As the quantity of sugar in the two solutions will be proportional to their respective volumes, and as the 6 c.c. of the "standard" solution contains 0.2 mgm. of glucose, the amount contained in the 8 c.c. of the unknown solution can be found out as follows:—

Standard.	Unknown.	Strength of glucose.
6 c.c. :	8 c.c. ::	0.2 mgm. : x
$\therefore x = \frac{8 \times 0.2 \text{ mg.}}{6} = 0.266 \text{ mgm.}$		

Now 0.1 c.c. of blood contains 0.266 milligram of glucose. Therefore, 100 c.c. of blood will contain 266 milligrams which is equivalent to 0.266 gram (per cent.).

PLATE I.

For easy calculation I have worked out a table which will give the results at a glance. Simply note the readings of the standard and that of the unknown in c.c.s and find out from the table the percentage of blood-sugar at once without going into calculations.

For the sake of convenience, the various steps in the estimation of blood-sugar may be summarized as follows:—

(1) Take 3.0 c.c. of distilled water in an extraction tube.

(2) Measure out 0.2 c.c. of the oxalated blood and add it to the distilled water (Plate I, A).

(3) Add 0.4 c.c. of 10 per cent. sodium tungstate, immediately followed by 0.4 c.c. of 2/3 N sulphuric acid in the extraction tube containing blood. Stir with a glass rod (Plate I, B).

(4) Filter into another extraction tube.

(5) Into a special 30 c.c. graduated tube take 1 c.c. of the diluted glucose solution containing 0.2 mgm. of glucose, and add 1 c.c. of distilled water to it. Mark this as "Standard." Into another similar tube, take 2 c.c. of the blood filtrate. Mark this as "Unknown." Add 2 c.c. of the alkaline copper solution in each of these two tubes. Shake.

(6) Put both these tubes in the boiling water bath for 10 minutes.

(7) Take the two tubes out of the boiling water bath and add 2 c.c. of phosphomolybdic acid to each. The two solutions turn blue. Shake by gently stroking the bottom of the tubes against the palm of the hand (Plates I, C & D).

(8) Put the two tubes inside the "comparator" (Fig. I) and very carefully add distilled water to the deeper coloured solution till the colours in the two tubes exactly match each other (Plates I, E & F).

(9) Take the readings in the two tubes in c.c. and calculate or read the results directly from the table.

A NOTE ON STABILITY OF SOLUTIONS OF CALCIUM HYPOCHLORITE INTENDED FOR USE IN SNAKE BITE.

By A. D. STEWART,

LIEUT.-COL., I.M.S.,

Professor of Hygiene, Calcutta School of Tropical Medicine.

The use of injections of 2 per cent. solutions of hypochlorite of lime and calcium hypochlorite

has been recommended by Calmette for immediate treatment in snake bite. He states that those solutions are effective and possess the advantage of not producing severe local destructive effects. It was suggested that outfits of ampoules containing hypochlorite solution might be useful for those exposed to the danger of snake bite, which would have the advantage of being cheap and easily replaced.

The question of the stability of such solutions under ordinary conditions arose and it was considered worth while to investigate this point. Solutions of calcium hypochlorite of approximately two per cent. available chlorine were kept for over one year and tested at intervals.

The following solutions were tested:—

I. A solution in amber coloured ampoules, sealed and kept in the dark and in the cool room at about 70°F.

II. A solution in amber coloured ampoules, sealed and kept in the laboratory at room temperature.

III. A solution in amber coloured ampoules, to which had been added N/10 sodium hydrate in the proportion of 1 to 10 of the hypochlorite, and kept in the laboratory at room temperature.

IV. Colourless ampoules of the same solution to which N/10 alkali had been added in the proportion of 1 to 10, and kept in the laboratory under ordinary conditions.

V. Colourless ampoules filled with a stronger solution (2.7 per cent. of available chlorine) and kept in the laboratory under ordinary conditions.

These solutions were periodically tested and the results of the test are shown in the table below:—

Specimen I lost about 5.5 per cent. of its original strength.

Specimen II lost over 50 per cent. of its original strength.

Specimen III lost over 50 per cent. of its original strength.

Specimen IV lost all of its original strength.

Specimen V lost all of its original strength.

These represent losses after storage for over one year. Under conditions of specimen I, the solution will keep with very little loss of strength under ordinary conditions; the addition of a small amount of alkali increases its keeping qualities to a slight extent.

The advantage of issuing in amber coloured ampoules is very marked.

The practical conclusion is that calcium hypochlorite solution stored in amber coloured ampoules and kept in a dark cold room will keep well, whereas the same solution under ordinary conditions would be likely to lose half its strength after one year, the addition of a small quantity of alkali being slightly advantageous. Ordinary glass ampoules are useless. It would be possible to make outfits of ampoules of hypochlorite solution for those exposed to the danger of snake bite, and if they were replaced at short intervals there could be at hand a remedy cheaper and

more effective than anything short of antivenene. The examinations of the solutions were carried out by Mr. Nani Lal Banerji, A.I.C., Assistant

These inoculations were given in February, August, and October; and chiefly to medical men and assistants and the menials who actually

School of Tropical Medicine.

THE VALUE OF INOCULATION IN THE PREVENTION OF CHOLERA.

By K. L. BASU MAILLIK, M.B.,
Chachasi P. O., Howrah District.

DURING the last six years I have been using anti-cholera inoculation for the prevention of cholera among the European and certain classes of Indian employees of a jute mill near Calcutta. Cholera is endemic in this part of Bengal, and cases occur throughout the year, whilst from year to year in the months of April and November the disease becomes epidemic. The country is entirely riparian and the natural ground level low (18.3 in.). There is about 60 inches of rainfall during the year.

1922.

This being the first year of use of the vaccine, there was great reluctance on the part of the Indians of *bhadralog* class to take it. The vaccine was brought out from Manila by my then colleague, Dr. F. H. Colby, M.D., on his way out to India from the U. S. A. The inoculations given were as follows:—

Europeans; adult males ..	29
Adult females ..	6
Boy ..	1
Girls ..	2
Indians; adult males ..	12
TOTAL ..	50

came into contact with cholera cases in the hospital. The majority of the Europeans (20 out of 29) received two doses, whereas the majority of the Indians only took one dose. There was but little local reaction to the inoculation, with the exception of a slight degree of local inflammation which subsided in 24 hours.

Among these 50 inoculated persons there was no case of cholera during the year.

1923.

During this year there was widespread epidemic cholera among the cargo-boat crews, and hence a number of boatmen were inoculated. The figures for the year were as follows:—

Europeans; adult males ..	6
Females ..	1
Indians; boatmen ..	25
Menials ..	3
TOTAL ..	35

These cargo boats are used for bringing jute and supplies from Calcutta to the mills and factories along the Hooghly. The boatmen are sturdy upcountry Mahomedans, and the crew of a boat consists as a rule of 5 or 6 men, including a boy cook. They are a healthy type of men, with malaria and cholera as their chief complaints. When leaving Calcutta they take a caskful of drinking water from the city, and when the supply runs out in mid-river (as it very often does), they fall back on the river water, which is a frequent source of cholera.

During this outbreak several *manjhis* (boatmen) died of cholera, whilst others were attacked and recovered. Hence the inoculation of 25 of

them, comprising about half the total employed. Subsequently it was noticed that no case occurred among the inoculated *manjhis*, although other cases continued to occur among the non-inoculated crews.

1924.

During this year there was no epidemic cholera, and hence no inoculations were carried out. One case of cholera was admitted in November and proved fatal; this was in an uninoculated boatman.

1925.

The inoculations were as follows:—

Europeans; males	22
Females	8
TOTAL			30

(All with two doses).

Indians; clerical staff, one dose only ..	28
Two doses ..	20
Sweepers; one dose only ..	7
Boatmen (<i>manjhis</i>), one dose only ..	30
Steam launch staff, one dose only ..	11
Contacts living in the same room as a cholera case, one dose only ..	4
Durwans, one dose only ..	4
<hr/>	
TOTAL ..	
<hr/>	
GRAND TOTAL ..	134

This year the vaccine used was imported from the Central Research Institute, Kasauli, and some 58 per cent. of the Indian clerical establishment of *bhadralog* class refused to be inoculated on account of the reaction; whilst some 42 per cent. were inoculated. The boatmen and the staff of the Company's steam launch came forward readily and brought their friends; those who had been inoculated in previous years also coming forward. In fact they were positive enthusiasts for the "*sui ka dawai*" (hypodermic medicine); and the readiness with which such illiterate, but simple minded and sturdy folk will come forward for prophylactic inoculation when they have realised its benefits speaks well for the future of such inoculations in India.

Reactions in general were slight, and did not last for more than 48 hours. A curious point noticed was that reactions were much less among those Europeans who played tennis immediately after the injection than amongst those who did not. During this year (1925) there were 4 cases of (clinical) cholera and 3 of acute diarrhoea among the boatmen, but all in non-inoculated persons. A further point to be noted was the absence, not only of cholera, but even of diarrhoea and other bowel complaints among the inoculated. The total cholera incidence during

the year among the entire personnel employed was 2.31 per mille.

1926.

Only 5 Europeans and 4 Indians were inoculated during the year; total 9 persons. The incidence of cholera amongst the villagers this year was very low; and only 16 cases—or 2.43 per mille—occurred among the Company's employees. The incidence was again confined to the non-inoculated. The cases occurred among the non-inoculated crew of a boat. The 5 Europeans inoculated were newcomers to the Company's staff from Ireland and America.

1927.

During the summer epidemic of this year a large number of inoculations were carried out. The figures were as follows:—

Europeans; two doses each adult	..	33
Indians; one dose each.—		
Clerical establishment	..	50
Contacts and menials	..	82
Boatmen	..	27
		<hr/>
TOTAL	..	192

The vaccine was again obtained from Kasauli through the office of the Director of Public Health, Bengal. There was no case of cholera among the inoculated persons, but 8 cases occurred among the non-inoculated in September among about 150 boatmen.

A peculiarity noted during this year was a delayed secondary reaction at the site of inoculation. For the first 48 hours after inoculation there was some redness and tenderness at the site of inoculation. This then subsided completely; but 4 to 6 days later swelling and tenderness recurred at the site of inoculation with greater severity and lasted for from 24 to 72 hours. This was especially marked in the series of single dose inoculations.

SUMMARY.

In all 420 inoculations with anti-cholera vaccine were carried out during the six years concerned; those inoculated being the European staff, numerous contacts, attendants in hospital on actual cases of the disease, the clerical establishment, and the boatmen who are frequently compelled to drink sewage-polluted Hooghly water. The 420 inoculations were given and distributed among a total personnel and establishment of about 280 persons. Among these 280 persons there were 32 cases of cholera during the six years concerned; but in every instance the patient was a non-inoculated person. The following table gives a summary of the series.

There is every evidence to my mind of the high degree of efficiency afforded by inoculation with anti-cholera vaccine in the prophylaxis of cholera.

Summary of Cholera Inoculations.

Year.	Europeans.	Indians.			Total.	Incidence of clinical cholera in the inoculated.	
		Middle or Babu Class.	Menials and Labour Contacts.	Boat Crew.		Inoculated persons including boat crew.	Uninoculated boat crew only.

A Mirror of Hospital Practice.

A CASE OF BALANTIDIAL DYSENTERY.

By BIJOY KRISHNA CHATTERJEE, M.B., D.T.M.,
(Bengal),

Assistant Surgeon, Assam-Bengal Railway Hospital,
Lumding, Assam.

L. M., a Hindu male, was admitted to the Assam-Bengal Railway Hospital, Lumding, for the treatment of chronic dysentery, from which he had suffered for the past fifteen years or so. His first attack had been about fifteen years previously; after that he had had three or four attacks at intervals of some three to four years. The previous attacks had not been prolonged, but the present one had persisted from February to November 1927, with remissions of only a few days at a time when he was free from symptoms. Each time he had been treated with injections of emetine.

He was very emaciated and weak, and slightly jaundiced in the eyes. On examination, the descending colon and sigmoid flexure were found to be palpable; the liver just palpable and tender; the spleen enlarged to about three finger-breadths below the costal margin, and tender. The stools as inspected macroscopically were semi-solid and dark coloured. No blood or mucus was noticed.

On microscopical examination of the stools the first day, nothing was found. On the second day, however, after a dose of magnesium sulphate, the stools were found to be full of motile *Balantidium coli*. (This finding was confirmed

by Dr. F. C. Lees, M.R.C.S., L.R.C.P., Medical Officer, A. B. Railway.)

After this finding the patient was put on to thymol, one 10-grain powder every hour, preceded and followed by 2 ozs. of magnesium sulphate, for one day. After this the stools were examined daily, and showed balantidia for five days. On the sixth day the thymol treatment was repeated. In the meantime, he was given daily an enema of 2 ozs. of 5 per cent. protargol lotion, and by the mouth a mixture containing iron and quinine citrate, nux vomica and liquor arsenicalis.

After the second thymol treatment the stools were examined on alternate days, and on two occasions *Balantidium coli* was found; the last time four days after the second course. After this the stools were examined daily for twenty days and no balantidia were found at any time. A protargol enema was given daily for ten days, and after that a simple enema of normal saline to counteract any possible cumulative effect of the protargol on the gut. A daily enema of quinine bihydrochloride, 1:1,000 was then given daily for eighteen days.

Finally, when his stools had become negative for *Balantidium*, the patient was put on a course of Yatren, one pill t.d.s., for seven days.

The patient gave a history of having taken meat in large quantities, but had never taken pig's flesh, and had had no association with either pigs or monkeys. He had eaten the flesh of porcupines frequently.

During his stay in hospital he suffered from severe colic on and off, and the only thing which gave him relief from this was small doses of tincture of *cannabis indica*. (It was found out that he was a *ganja* smoker.) His appetite was poor at first, but later on improved much, as also did his general health. There was no pyrexia during his stay in hospital.

He was discharged (?) cured on the 36th day after his admission.

Remarks.—The case is of interest from several points of view.

(1) *Balantidium coli* infection is very rare in India; so much so that Byam and Archibald do not mention its occurrence in India, though Major Knowles mentions its occasional occurrence in this country, and especially in Assam.

(2) The patient had not been associated in any way with pigs or monkeys—the natural hosts of *Balantidium coli*.

(3) The patient's frequent meals of porcupine flesh. Is the porcupine still another host of *Balantidium coli*?

(4) The apparent cure by thymol and protargol treatment. *Balantidium* infections are notoriously difficult to eradicate.

(5) The severe abdominal colic, perhaps due to his not having access to *ganja*, and cured by a few small doses of *cannabis indica*.

My thanks are due to Dr. F. C. Lees, my medical officer, for kindly permitting me to send a report on this case for publication.

A CASE OF CEREBRO-SPINAL MENINGITIS WITH RECOVERY.

By K. M. BASU, M.B.,

LATE CAPT., I.M.S.,

Assistant Surgeon, Uluberia Hospital, Howrah District.

On the 29th August, 1926, I was called in to see a patient, N. K. Ray, a Hindu male, aged 25 years suffering from continuous fever with intense headache of five days duration. The patient had had no sleep for four nights owing to the headache, whilst the temperature had ranged from 100 to 101°F.

Some years previously the patient had had syphilis, for which he was treated with injections of some preparation of arsenic. He had also had pneumonia with pleurisy some two years previously, and had had an attack of herpes on the chest fifteen days prior to onset of his present illness. He takes alcohol and country liquors

perchloride mixture prescribed. Hexamine, 10 grains, was given twice daily, and chloretone, 10 grains, prescribed for sleep at night. Blood films were sent to the Calcutta Clinical Research Association; the report was that no malaria parasites were found, and that the differential leucocyte count showed polymorphonuclears 77 per cent., small mononuclears 17 per cent., and large hyaline mononuclears only 6 per cent.

30th August.—Headache much less, but temperature went up to 103°F.

31st August.—Headache has practically disappeared. The relief with continuous potassium iodide treatment appears to indicate a syphilitic origin to the infection. Potassium iodide and urotropine continued.

1st September.—There was a sudden and severe return of the headache, with neck retraction, semi-delirium, and fever, 102°F. The patient was restless throughout the day. Lumbar puncture was now decided on, but it was decided

Name... N. K. Roy. Cast... Bengalee. Age... 27 years. Disease... Cerebro-Spinal Meningitis.
Attack... 24th August 1927. Result... Cured. Date of Result... 12.9.27.

in fair amount, and has had malaria off and on. The fever had commenced with rigor and pains all over the body on the 25th, with onset of the severe headache on the evening of the 26th, whilst stiffness of the neck had appeared on the 29th—the day of my first visit to him.

On physical examination, the neck was found very stiff and painful on movement; the pupils widely dilated; and photophobia present, with great sensitiveness to noises. Kernig's sign was positive, but Babinski's sign negative. The knee jerks were exaggerated and no skin rash visible. The liver was enlarged to three finger-breadths below the costal margin, and the spleen was not palpable. The lungs and heart appeared to be normal. The bowels had been constipated from the beginning of the illness.

A provisional diagnosis of meningitis (? syphilitic) was made, and calomel in divided doses, together with a potassium iodide and hydrarg.

to await the arrival of anti-meningococcus serum before carrying it out. Chloral, bromides, and chloretone were given.

2nd September.—Condition no better; if anything, worse. Lumbar puncture was carried out, and the fluid withdrawn came out with great force and proved to be turbid; some 25 c.c. of fluid was withdrawn, the fluid spurting out as if an artery had been cut. An equal amount of anti-meningococcus serum was injected inside the theca. The cerebro-spinal fluid removed was sent to the Clinical Research Association in Calcutta for examination. Their report, received two days later, was that it was faintly turbid; contained no glucose; gave a negative globulin test; showed 1,000 leucocytes per c. mm.; with a content of 94 per cent. polymorphonuclear leucocytes, and 6 per cent. small mononuclears. Gram-negative, intracellular diplococci were present in the stained smear. Culture had yielded

sterile results. Later on, a growth of meningo-cocci was obtained.

On the evening of the 2nd, within six hours of the lumbar puncture, the temperature dropped to normal for the first time, with simultaneous disappearance of the headache and neck rigidity. For the next two days the patient's condition rapidly improved.

5th September.—The patient's temperature oscillated between 100 and 102°F., but with no return of the headache or stiffness of the neck.

7th September.—The temperature was still elevated to over 101°F., and a second dose of 50 c.c. of anti-meningococcus serum was given intramuscularly. Within six hours the temperature dropped to normal, and continued so with the exception of a rise on the 10th and 11th September.

Quinine was now administered, and the patient's history thereafter was uneventful; recovery being complete.

Remarks.

(1) There was no record of any recent cases of cerebro-spinal fever in the locality, whilst the patient had not left his home for a long time previously. Further, the previous history of syphilis strongly suggested a syphilitic infection of the spinal cord.

(2) On the other hand, the signs and symptoms presented were typical of cerebro-spinal fever; e.g., fever, severe headache, stiffness of the neck, and a positive Kernig's sign. In all such cases where diagnosis is obscure a lumbar puncture should be carried out. In the present case this was done with the ordinary long stout needle included in my pocket surgical aid case, intended for subcutaneous administration of normal saline.

(3) The terminal rise of temperature and the final influence of quinine in restoring a permanently normal temperature leads one to suspect that latent malaria may have had an element in the case.

A CASE OF LYMPHATIC LEUKÆMIA.

By J. M. GHOSH, M.B. (Cal.), D.P.H. (Lond.),
D.T.M. & H. (Cantab.),

Chief Medical Officer, Keonjhar State, Sadar Hospital,
Keonjhar, Balasore.

MANGAIKOL, aged 25, single, Hindu male cultivator, was admitted to hospital for severe abdominal colic on the 29th August, 1927.

The hospital records showed that he had been an in-patient in the same hospital seven months previously for the same complaint, and had been discharged cured (?) after a fortnight. He gave a history that the colic had lasted on and off for about a year, lasting each time for a variable period, having no relationship to food, and being localised around the umbilicus. It had never been very acute.

On examination, the patient proved to be of poor physique, with a rather dull intelligence. His abdomen was covered with scars,—the result of application of counter-irritants. He was definitely anæmic. The family history elicited nothing of importance, and he denied all history of previous dysentery, diarrhoea, fever, or hæmorrhage from the intestine or elsewhere; in fact he stated that he had been generally healthy.

Physical examination failed to detect any enlargement of the spleen or liver; the lungs and heart appeared to be healthy; the pulse was soft and quick, however. The stool emulsion—examined in direct smear without concentration—showed *Ankylostoma* ova present. The urine was alkaline, free from albumin and sugar, and showed a deposit of amorphous and triple phosphates.

Blood examination, however, gave the following quite unexpected picture:—

Red blood corpuscles 2,050,000 per c.mm.

Total leucocytes 75,000 per c.mm.

Polymorphonuclears 4 per cent.

Lymphocytes (of chronic type) 96 per cent., whilst a few Rieder's cells were present, and megaloblasts. No malaria parasites were encountered.

On re-examination of the patient clinically, the inguinal and femoral glands on both sides were found to be fairly discrete and tolerably hard, but individually no bigger than the nose of a service revolver bullet. The area over the sternum was resonant throughout, and no other glands were palpable in any region of the body.

The patient remained in hospital for only a week,—the sight of a patient being brought into the ward from the operation theatre on a stretcher scaring him away. Although he gave no history of fever prior to his admission to hospital, his temperature in the evenings when in hospital ranged from 99 to 101.6°F., and in the mornings from normal to 99°F.

In this case there were practically no signs or symptoms. The mild abdominal colic might possibly have been due to the hookworm infection. But for the microscopic diagnosis the patient might have been submitted to treatment with all the gastro-intestinal sedatives in the Pharmacopœia.

A CASE OF IMPERFORATE ANUS.

By INDRA MAN.

Assistant Surgeon, Chancha Hospital, Bhadgaon, Nepal.

A. K., a male infant, three days old, was brought to this hospital with the complaint that there had been no motion since birth.

On examination a pin-track was found leading towards the rectum, but there was no communication of the gut with the exterior. Also there was no bulging of the perineum when the infant

cried. The abdomen was somewhat distended, but the child was obviously not in distress, and no distension or other abnormality could be detected on abdominal palpation.

Operation.—As I was afraid of toxic infection in such a tiny baby, no anæsthetic was given. An incision, some $1\frac{3}{4}$ inches in length was made from the pin-track anteriorly, and enlarged posteriorly. After dissection to a depth of some $2\frac{1}{2}$ inches the gut was recognised by its white appearance. It was free on its posterior aspect, but attached anteriorly. The adhesions were snipped through and the gut brought down to the aperture of the wound. A puncture having been made into it, black tarry liquid was evacuated. It was then stitched to the parietes, and a continuous silk suture applied. A drainage tube was inserted for the fæces to escape, and the whole wound packed with antiseptic dressings in the hope of keeping the parts clean.

Post-operative Treatment.—As the infant's mother refused to stay in hospital, it was advised that the child should be brought to hospital twice a day for changing the dressings. By the second day the sphincter had assumed its function, as shown by its red and rugose appearance. The wound became infected in its posterior part despite all antiseptic precautions, but healed by granulation by the twenty-first day. There were no complications, and the infant made a splendid recovery, with a functional anus.

Remarks.—I have previously had cases of imperforate anus in infants here occasionally, but they did not usually survive for more than three or four days. My own impression is that cases, such as the above, can only be saved by immediate operation. The parents deny all history of venereal disease, and one would like to know the causes of such congenital malformations.

The baby is now three months old, and is apparently perfectly healthy.

A CASE OF CHRONIC AMŒBIC INFECTION, ESPECIALLY AFFECTING THE VERMIFORM APPENDIX.

By J. BA CHOW, I.M.P.,

Sub-assistant Surgeon, Civil Hospital, Syriam, Burma

CHILAM, Mohammedan male, age 26 years, coolie, a resident of Durga Ward, Syriam, was admitted into this hospital on the 16th July, 1927, for the treatment of emaciation, œdema of the feet and frequent loose watery motions.

Ten months previously he had suffered from dysentery for about a month, and since then he had had recurring attacks of diarrhoea in spite of treatment. Various forms of medical treatment were tried one after another for over six weeks without improving the patient's condition. It was then decided to lavage the large bowel through a cæcostomy opening, and the operation

was done on the 2nd September, 1927, under spinal anæsthesia. As the appendix was found thicker than normal, of a very firm consistence, and slightly adherent, with a concretion at the tip, it was removed during the operation.

On opening the lumen of the appendix, a small collection of fæces was found at the tip, with muco-pus in the rest of the lumen. A smear of the latter was examined under the microscope and showed numbers of active *Entamæba histolytica*.

The interesting point in this case is that no amœbæ were found in repeated examination of the stools, while the appendix literally swarmed with them. This probably accounted for the resistance of the patient to treatment. He now has regular formed stools and can take full diet without any inconvenience.

I am indebted to Dr. W. B. Crawford, Superintendent of the Civil Hospital, Syriam, for permission to publish this case.

APOMORPHINE HYDROCHLORIDE IN THE TREATMENT OF PERSISTENT HICCUGH.

By R. C. PANDA, I.M.P.,

Parikud, Puri District.

APOMORPHINE hydrochloride is said to be the most powerful emetic in the British Pharmacopœia, and as such it is extensively used in cases of poisoning. As an expectorant also it is prescribed in cases of chronic bronchitis. I have never however seen it used for other conditions. Professors Savill and Osler advocate the use of the drug (in doses of $1/10$ th to $1/8$ of a grain) in cases of hiccough, but they do not explain how the drug acts in checking that distressing symptom.

Two and a half years ago I had to treat a very severe case of persistent hiccough, while at Parlakimedi, Ganjam District. I tried almost everything that I could think of, until—finally—a single injection of apomorphine completely cured the patient of his very distressing symptoms. Curiously enough, the patient did not vomit, and the drug appeared to have effected a complete cure.

Since then I have relied on this drug for the treatment of persistent hiccough. Only a few days ago I had such a case, and gave two injections, one each on alternate days. The patient had slight vomiting after both injections, but I was careful to give the drug on an empty stomach, so that he vomited only bile and gastric juice.

I would be much obliged if any of your readers can kindly enlighten me on the action of the drug in these cases of persistent hiccough, and why little or no vomiting occurs, when the drug is administered in such cases.

Indian Medical Gazette.

FEBRUARY.

"DIATHESIS."

THE "blessed word diathesis" used to be in constant employment by medical men, its use gave us a comfortable feeling of erudition and covered a great mass of ignorance. Nobody dared to question the existence of a condition which had been accepted by generations of medical men, and it was nothing short of rank heresy to raise doubts as to the importance of the influence exerted by diathesis. At a later date it became the fashion to demand evidence before any dogma was accepted, and when most of the diseases which had been regarded as diathetic were found to be due to bacteria or faulty diet the term diathesis with all its implications was almost abandoned.

The pendulum is now swinging back and an authority like Sir Archibald Garrod calls attention to the importance of diathesis: he points to the renewed attention which is being paid to the subject, especially in Germany, and asks for renewed study of its influence in the causation of disease. Sir Archibald does not clearly define the word diathesis, but he excludes acquired tendencies to disease, and limits the use of the term to inherited bodily conditions which predispose to some diseases. He says that it is indisputable that some individuals, families and races are far more liable than others to particular diseases and regards this basal fact as the foundation on which the various doctrines of diathesis are built. Basal facts are simple and solid in themselves but they are capable of sustaining a variety of less substantial superstructures in the form of explanations, and it is by no means safe to assume that a basal fact like the frequency of diabetes or gout in some families or races is capable of only one interpretation. It is a basal fact that tuberculosis is especially common in some families, yet the tuberculous diathesis is no longer a self-evident proposition; its very existence is difficult to prove, now that so much is known of the part played by environmental factors in the causation of the disease. It is a basal fact that diabetes is very common in some families in Bengal, but it is not right to assume that the true explanation of the fact lies in an inherited diathesis. Two important considerations have to be taken into account: one is that the families concerned have adopted habits of diet and exercise which differ from those prevailing among the families which are free from diabetes, and the other is that families which have sprung from the same stock as the diabetic families but live under different environmental conditions are not specially prone to the disease.

It is a basal fact that cancer of the penis is far commoner among Hindus than Mahomedans,

but the environmental factor of circumcision is far more likely to explain the immunity of Mahomedans than an inherited diathesis.

Sir Archibald points to the gouty diathesis as one of the great examples of an inherited tendency to disease. He writes "in gout we are confronted with a highly hereditary malady presumably based on an inborn defect." But we are told by others that gout is a "disappearing disease" and that the offspring of gouty parents seldom suffer nowadays from gout. In this case also is it not possible that the well known tendency of some families to adopt faulty methods of eating, drinking and exercise may be the true explanation? In this connection it is necessary to indicate a common fallacy which is that environment first comes into play at birth; we are prone to forget that a most important period of life is spent in the mother's womb and that nourishment during this period consists of materials derived from the mother's blood, so that even if we were to find that the infants of gouty mothers showed differences in blood composition from those of other mothers we should not be justified in attributing the difference to inherited characteristics.

Environmental factors are complicated and elusive; they may begin to act several months before birth, and it is only when they can be satisfactorily excluded that we are justified in asserting that heredity is the chief factor concerned in the causation of any disease.

If inherited malformations and some diseases like Friedrick's ataxy were included as diathetic diseases it would be possible to prepare a long list of diatheses, but if we simply regard these as inherited diseases the proven cases of diathesis become very few.

It is natural and easy to believe that inherited tendencies to many diseases do exist in families or races but the stock examples like the tendency of Jews to diabetes, of negroes to tuberculosis, and of indigenous populations to yellow fever are capable of explanation on environmental grounds. It is not asserted that inherited diathesis is non-existent, it probably does exist and it may prove to be a very important factor in the causation of disease. On the other hand it is unquestionably a wise policy to make an exhaustive search for environmental faults which can be remedied before we fall back on the paralysing and fatalistic view that the diathesis is to blame.

With regard to racial susceptibility to disease, it is important to note that most of the diseases which are known to be inherited have a world-wide distribution, so that inborn structural defects appear to be cosmopolitan. In the same way special susceptibilities to diseases, vaccines and drugs are also found in some individuals among all races, they have rarely been shown to occur in one race and to be absent in others. Such isolated examples as the great mortality from measles in newly affected populations are

unexplained, but they are possibly due to a complete absence of acquired immunity in the populations concerned, in other words to the lack of an environmental factor which protects the other peoples of the world.

There is no satisfactory explanation of the remarkable changes which have taken place in the virulence of small-pox and scarlatina in European countries within the past few years, but we do not assume that the changes are due to the elimination of a special diathesis.

The truth is that our powers of observation are defective, and it is better for us to admit the fact rather than to adopt plausible explanations or to take refuge in pseudo-scientific words like "diathesis," "functional," "idiopathic," and the like. In such words there lurks a potent suggestion, viz., that we understand the condition to which the high-sounding name has been applied, whereas our real condition is one of mental fog.

Taking these considerations into account, it is perhaps better that the word diathesis should remain enshrined as a relic of the days when accurate observation was at a discount and dogma swayed the minds of men. The term "inherited tendency to a disease" will serve very well to express the idea which underlies the word "diathesis" and will be less likely to cause misleading suggestions. To sum up the whole matter, our efforts should be directed chiefly towards the discovery and removal of errors of environment; when these have been exhaustively dealt with we may fold our hands and admit that heredity is responsible for the rest.

CALCUTTA STUDENTS' HEALTH.

THE report on the Students' Welfare Scheme of the University of Calcutta for 1926 is an interesting document. Its special value is that it supplies detailed information of the health and physical standards of large numbers of students in Calcutta and its suburbs.

The most disquieting feature is that there is some evidence of an increase in the "general defects" and in the standards of physical development. Two out of every three students show some defect, and it is obvious that the health of the Bengali young men calls for careful investigation.

A few of the outstanding points brought out in the report are noteworthy.

About 44 per cent. of the students show a "stooping" gait and the percentage is greater among the younger students.

The rate of growth in height between the ages 16—18 is four times greater than between 18—21, while the rate of increase of weight is three times as great between the ages of 18—21 as in the age group 16—18.

A diet table drawn up by Rai Bahadur Dr. Chuni Lal Bose is of interest; this consists of rice 6 oz., wheat flour (*Ata*) 10 oz., pulses (*Dal*) 3 oz., fish 5 oz., potatoes 6 oz., other vegetables 8 oz., ghee $\frac{1}{2}$ oz., mustard oil 1 oz.,

sugar 1 oz., salt 1 oz. This represents about 90 grammes proteins, 70 grammes fats, 468 grammes carbohydrates, and 2,800 calories. This diet differs from the usual Bengali scale in containing more wheat flour than usual, and a recommendation is made that 4 oz. fresh milk curds should be supplied to those who object to fish. The cost of the diet is about $8\frac{1}{2}$ annas at prevailing market rates. Fresh fruit is recommended when in season.

It is certain that pure fresh milk would be a valuable addition to this diet if it can be supplied within the available budget, and that fresh fruits should form a normal item of the diet, otherwise the diet scale appears to be quite satisfactory. It is likely that most students will buy extras when they can afford to do so.

The students fall within the following age groups. 16-17, 816; 17-18, 2,155; 18-19, 2,542; 19-20, 2,589; 20-21, 1,929; 21-22, 1,153 and 22-23, 788. Over 23 there are about 600.

The caste distribution shows 31 per cent. Brahmmins, 28 per cent. Kayasthas, 7.68 per cent. Mahommedans, nearly 2 per cent. Christians, and the rest belong to "other castes." About 30 per cent. of the students are returned as "thin," about 15 per cent. as "muscular" or "stout," the rest being returned as "medium."

The "thin" students are 34.4 per cent. in the 16-17 age group and 19.5 per cent. in the 21-22 age group, while the muscular and stout increase from $7\frac{1}{2}$ per cent. in the 16-17 group to $16\frac{1}{2}$ per cent. in the 21-22 age group, so that there is a tendency to put on flesh in spite of the adverse conditions of life. The students are classified according to complexion: the Brahmin students are rather fairer than those of other castes, but the differences are not striking, except that the Kshatriyas have a larger proportion of very fair students and a smaller proportion of very dark ones than any of the other groups.

The average heights and weights for the various age groups are:—

	15-16	16-17	17-18	18-19
Height ..	163.45 mm.	164.19	165.42	165.99
Weight ..	47.07 kilo	48.28	49.34	49.60
	19-20	20-21	21-22	22-23
Height ..	166.18	166.41	166.55	166.18
Weight ..	50.95	52.02	52.42	52.92

The average chest measurements on inspiration range from 80.38 cm. in the 16-17 age group to 84.36 cm. in the 22-23 age group. Chest expansion in cm. averages 4.01 and 0.587 in the same groups. The vital capacity in litres is 2.55 and 2.95 in these groups. It is surprising to learn that the acuteness of hearing, which was represented by the figures 54.7 and 57.8 for the right and left ears respectively in 1921, has risen to 72.83 and 79.09 in 1926. The conditions under which the tests were carried out are stated to have been unsatisfactory but the observers are convinced that the left ears are more acute than the right and also that the acuteness of hearing falls off from the age of 15 till 24, the figures

for various ages (right ear) being 15-16, 84.2; 18-19, 73.41; 23-24, 65.28.

The variations in the strength of grip are interesting; at the age of 15-16 the grip of the right hand in kilos is 32.11; it rises steadily till the age of 21-22 is reached when it is 40.83; then it falls and in the 25-26 group it is 39.02.

About one-third of the students show defects of refraction and no less than three-fourths of the defectives fall within the category of ± 5.2 to ± 5.0 diopters. Only $17\frac{1}{2}$ per cent. of those who need glasses are provided with suitable glasses and $62\frac{1}{2}$ per cent. have none at all. Here is a defect which could easily be remedied.

Dental caries occurs in about 8 per cent.; as many as 19 per cent. have bleeding and spongy gums, but only 4.5 per cent. have pyorrhoea. Presumably the bleeding and spongy gums are the precursors of the pyorrhoea which is almost universal in later life. It would be interesting to classify the state of the gums according to age. The teeth are said to be defective in some way in about 33 per cent. of cases.

About 27.5 per cent. of the students have some form of skin disease, especially ringworm, pityriasis versicolor and acne. Three cases of leprosy were detected among 12,705 students. This is an exceedingly small number, but it is likely that any student whose disease is conspicuous would already have been excluded, and it is also likely that early manifestations of the disease would not be detected during a hurried examination.

Among general defects we find that 4.6 per cent. suffered from heart defects, 0.47 from lung disease, 0.66 from liver defect, about 2 per cent. had enlarged spleen, 12.31 per cent. had diseased tonsils, nearly 1 per cent. had hydrocele, over 1 per cent. had "orchitis." Other points of interest will be found in the report which is issued by the Calcutta University Press.

This shows clearly that the students are defective before they come to the colleges, the life at the colleges does not appear to accentuate the damage which has been done but rather the reverse. It is obvious that the physical condition of the Bengali school-boy needs to be seriously investigated with a view to devising means of giving him a better start in life. The conditions under which college students live are perhaps not so bad as those of the school-boys, but they call for great improvement and the report of the Students' Welfare Committee will serve a useful purpose if it awakens the conscience of the Calcutta University and the general public to the urgent need for a health campaign among school children and students.

Calcutta Branch of the B. M. A.

It is proposed to form a Calcutta Branch of the British Medical Association. The territory included under the branch will be that known as the Presidency Division and the part of the Burdwan Division which is south of the Ganges. Will any medical men who are interested kindly communicate with Lieut.-Col. R. Knowles, Calcutta School of Tropical Medicine, Central Avenue, Calcutta?

SPECIAL ARTICLES.

THE USE OF SANOCRY SIN IN PULMONARY TUBERCULOSIS.

By Y. G. SHRIKHANDE, M.B., B.S., B.Sc.,
Resident Medical Officer, King Edward VII Sanatorium,
Bhowali, U. P.

ATTEMPTS have been made for some time past in the field of chemotherapy with a view to find a remedy for tuberculosis. Various compounds of copper, gold, manganese, glucinum and other metals and various derivatives of chaulmoogra oil and cod-liver oil have been tested. Nothing definite or convincing was brought to light, however, until about two years ago, bright and hopeful news came from Denmark and it was at once received with keen sympathy all the world over.

Sodium-thiosulphate of gold has been introduced in the treatment of phthisis by Professor Moellgaard of Copenhagen. Sanocrysin is the name given to this compound by him. It is an inorganic gold compound containing the negatively charged ion AuS_2O_3 to which its therapeutic properties are said to be due. It is a snow-white crystalline substance consisting of long, silky, glistening needles. It is a stable compound and remains unchanged when kept dry in sealed ampoules for at least one year. It is readily soluble in water.

Moellgaard believed that sanocrysin was a chemotherapeutic remedy that brings about destruction of tubercle bacilli, and in doing so, it liberated a certain amount of toxic substances. Recent investigations have shown definitely that the action of sanocrysin is due not to the destruction of the bacilli but to its action on the tuberculous tissue itself. This assumption is supported by the fact that the direct bactericidal influence of sanocrysin on tubercle bacilli *in vitro* is very insignificant. It has been suggested that sanocrysin brings about the decomposition and destruction of exudative tissue as a result of which certain protein-containing substances are produced which circulate in the blood and stimulate the various defensive forces of the body. This leads to increased phagocytosis and formation of anti-tuberculous products which ultimately bring about increased fibrotic growth round the foci of the disease. The curative effects of sanocrysin, therefore, appear to be due to the anti-tuberculous substances which it produces by its action on the tuberculous lesions. Of the initial theoretical foundation of Moellgaard, therefore, hardly anything remains to-day.

It is now recognised that sanocrysin has a metallic action and can act as a metallic poison by virtue of its gold content. It has a tendency to cumulative effects if given in large doses or at frequent intervals, or to persons who are unable to excrete it properly.

After administration sanocrysin diffuses quickly into the tissues. Only about 50 per cent. of gold is eliminated through the kidneys and intestines, chiefly the former. The remainder is retained in the tissues for a long time, especially in the liver and muscles. Elimination by the kidneys begins early and goes on for several weeks, so that a definite amount of gold is present in the circulating blood for two weeks at least. The largest amount is present in the first week and if the drug is administered before the week is over, cumulative effects are likely to appear. Sanocrysin, therefore, behaves in the body in the same way as other heavy metals.

Selection of Cases.—The acute pneumonic type of pulmonary tuberculosis is said to be best suited for sanocrysin treatment, especially in its early stages. In chronic tuberculosis of the lungs the following factors must be considered:—

- (1) The extent and accessibility of diseased foci.
- (2) The degree of resistance possessed by the patient.
- (3) The state of efficiency of the eliminative mechanisms of the body.

Good results are obtained in exudative (caseous) cases of not more than twelve months' duration. In productive (fibrotic) type of cases of long standing, with few or no blood vessels, it is obvious that the drug cannot penetrate through; hence these cases are not suitable for sanocrysin treatment.

Speaking in general terms, the advanced and toxic type of patient is unsuitable for sanocrysin treatment; while a relatively recent case, still well nourished and with some degree of control of his temperature, is likely to do well. A strong heart and not too well-marked toxic symptoms are essential for treatment. The drug is also said to be indicated in cases of hæmoptysis in order to prevent the tubercle bacilli from spreading throughout the lungs.

Contra-indications.—It should be kept in mind that the treatment engages the power of resistance to a certain degree. Anything that affects the resistance of the patient should, therefore, be considered as a contra-indication. The following are the contra-indications for the use of sanocrysin:—

- (1) Slight and early limited lesions which can be cured by conservative methods.
- (2) Chronic fibroid lesions.
- (3) High fever.
- (4) Extensive disease of long duration.
- (5) Renal and intestinal tuberculosis.
- (6) Tubercular meningitis.
- (7) Pre-existing tubercular disease of other organs, healed or active, e.g., surgical tuberculosis combined with fistulas and abscesses.
- (8) Highly intoxicated cases having no power of resistance, as indicated by failure to gain weight when at rest, irregular temperature, high sedimentation rate, etc.
- (9) Organic diseases of organs like the liver, spleen, kidneys or lowering of functional efficiency of the liver or kidney.

Dosage.—Moellgaard, believing in the chemotherapeutic action of sanocrysin, advocated large doses of 0.5 to 1.5 grammes at frequent intervals. The severe toxæmia and the "tuberculin shock" which resulted from this method of administration could not in all cases be relieved or prevented by the administration of the antitoxic serum. Moreover the serum made things worse by producing serum-sickness in addition to the already existing depressed condition of the patient. The dangerous consequences of this method of administration have, therefore, resulted in the modification of dosage. The present tendency is (1) to begin with small doses, (2) to administer the drug at long intervals, and (3) to avoid the use of the serum, which in itself is very trying to the patient and quite unnecessary if the shock can be avoided.

The modern dosage, as generally used in the West, is from 0.1 to 0.25 grammes increasing up to 1.0 gramme with intervals of about seven days between the injections. The maximum dose is repeated until the desired effect is produced. This finishes a course. If a second course is necessary, it is usually given after an interval of not less than two months.

In severe and pyrexial cases and also in women it is safer to begin with smaller doses and allow longer intervals. The golden rule to remember is not to give the next injection before the reaction from the previous one has passed off.

Some physicians give a hypodermic injection of caffeine after every dose of sanocrysin, apparently to counteract the depressing action of sanocrysin on heart.

In India, owing to the weaker constitution of Indian patients as a rule, it is better to start with smaller doses and give sufficient intervals between them. The initial course of injections should be somewhat as follows:—0.1, 0.2, 0.35, 0.5, 0.65, 0.75, and 1.0 gramme. The last dose is seldom reached in Indian patients. The maximum, or to be more precise, the optimum dose for a patient should be repeated until the desired effect is produced. In febrile and weak patients it

may be necessary to begin with 0.05 gramme. Some physicians repeat the first (initial) dose until the patient is able to tolerate it. Larger doses are then given until the optimum is reached.

The doses mentioned above are by no means the absolute rule. Variations may be made in them according to the needs of the particular case. For the subsequent courses it is not necessary to begin with small doses like the initial course. The subsequent courses may be arranged somewhat like this:—0.25, 0.5, 0.75, and 1.0 gramme.

It may be mentioned here that sanocrysin is supplied in ampoules containing respectively 0.1, 0.25, 0.5, and 1.0 gramme. It is not difficult, therefore, to make the required doses by various combinations of these quantities.

Mode of administration.—The clinical administration of sanocrysin is best performed by intravenous injection. A solution in distilled water of about 5.0 per cent. is almost isotonic with blood and should be used for intravenous injection. When the veins are not accessible for intravenous injection, e.g., in some women and children intramuscular injections are advised. In such cases a 3.0 per cent. solution of the drug is advised in order to avoid symptoms of irritation. Subcutaneous injection is not advisable owing to the risk of skin necrosis. Accidental perivascular injection causes a little swelling and soreness at the site of injection but necrosis does not occur if aseptic precautions have been observed. Care should be taken about the distilled water just as with salvarsan.

As mentioned above a 5.0 per cent. solution is isotonic with blood. Therefore it will be noticed that for purposes of intravenous injection 2.0 c.c. of distilled water are required for every 0.1 gramme of sanocrysin.

An all-glass syringe with side nozzle of 20 c.c. capacity should be used, so that a full dose of 1.0 gramme can also be given with it. A platinum needle should be employed. An ordinary steel needle is acted upon by the drug and is, therefore, not safe. For the same reason a "Record" syringe is not advisable. The syringe and needle should be thoroughly sterilized in boiling water.

Distilled water should be used for making the solution and it should be boiled again at the time of making the solution. In short, the same precautions should be taken about the use of water as in the case of salvarsan.

The required quantity of water should be drawn into the syringe. The top of the ampoule should then be filed off and the solution made in the ampoule itself. The solution is then drawn direct into the syringe. The injection should be given as soon as possible after it is ready. The veins at the bend of the elbow are best suited for injection. The skin may be sterilised by rubbing ether on it, but if tincture of iodine is used it should be wiped off, when dry, by rectified spirit so that the vein may become visible. The needle should be passed through a flame just before it is inserted into the vein in order to be sure of sterilisation. When the needle is in the vein (as will be known by the presence of blood in the syringe) the solution should be slowly and steadily pressed into it.

In some patients, especially females, it is found difficult sometimes to get the vein. In such cases it has been found that the operation is much facilitated by "feeling" for the vein with sterilized fingers. It is far easier to feel the course of the vein than to see it. I have never found any difficulty by this method.

The injection should preferably be given in the morning, and the patient undergoing the treatment should preferably be kept in bed as long as the treatment lasts.

During the course of treatment it is necessary to examine the urine at least twice daily—morning and evening—for albumen and casts. It is also necessary to record the temperature three or four times daily. Other symptoms should also be looked for, e.g., metallic taste in the mouth, ulcers in the mouth and on the tongue, etc. It is for the doctor to look for these

signs and symptoms and not wait for the patient to exhibit them. They may necessitate the interruption of treatment for the time being at least.

As mentioned above, with the cautious use of sanocrysin, the administration of antitoxic serum has been rendered unnecessary. If, however, at any time symptoms of toxin or tuberculin shock appear, the antitoxic serum may be used. The clinical administration of the serum is most easily done intramuscularly, but in case of urgency it should be given intravenously. The time of absorption by intramuscular injection is between 16 to 24 hours. When intravenous injection has to be given, desensitisation should always be carried out immediately before the injection to avoid anaphylaxis. This is easily done by giving 0.5 c.c. of the serum intravenously, then waiting for a minute or so, and then slowly injecting the rest of the serum.

In cases where a fresh serum injection has to be given after a week from the previous one, desensitisation must always be done by intramuscular injection of 2.0 c.c. of the serum a day before.

Reactions and Complications.—These are very common in the treatment of sanocrysin. They are as follows:—

(1) Temperature reactions:—These may occur in three ways:—

- (a) Short, immediate:—3 to 10 hours after the injection as a sudden rise followed within a short time by a fall.
- (b) Prolonged:—a gradual rise during the day of the injection, followed by a gradual fall.
- (c) Delayed:—rise occurs after the second day or so and remains continuous for days.

The temperature reactions are as a rule accompanied with headache and pain in the limbs and joints.

(2) Gastro-intestinal disturbances, e.g., nausea, vomiting, diarrhoea, anorexia, and hiccough.

(3) Loss of weight.

(4) Albuminuria and cylindruria:—Occur in two forms:—

(a) Early:—occurring in connection with other reactions and shortly after the injections. As a rule disappears soon and spontaneously.

(b) Late and independent:—occurring later on in treatment. Is due either to too rapid increase in doses or to too short intervals between the injections. Lasts for a long time.

(5) Ulceration of the mouth and tongue.

(6) Skin reactions:—Varying from ordinary skin rashes to actual dermatitis of exfoliative type.

(7) Focal reactions:—Temporary increase in expectoration and transient increase in râles.

(8) Toxin or tuberculin shock:—Rarely seen with the present modification in doses. Shown by a fall in temperature, cardiac asthenia, and albuminuria.

(9) Jaundice.

(10) Hæmoptysis.

No fresh injection should be given until all the reactions from the previous dose have passed off. Some of them may necessitate interruption of the treatment temporarily.

Danger Signals.—Not only is it necessary to look for albumin in the urine but the quantity of urine excreted during 24 hours should also be noted. Marked diminution in the daily excretion of urine should be regarded as a danger signal. So also the occurrence of small aphthous ulcers on the tongue and buccal mucous membrane. The mouth should be examined for a few days after every injection. Gastro-intestinal disturbances and a metallic taste in the mouth are also danger signals which must be kept in mind. These danger signals necessitate caution in the administration of the drug.

Conclusion.—The favourable effects of sanocrysin are found in the remarkable improvement that it sometimes causes in the physical signs. This change in tissues of the chest can be corroborated by skiagrams

taken before and after a course of sanocrysin. If possible, therefore, x-rays should be employed during the course of treatment. Sanocrysin also reduces the number of tubercle bacilli in the sputum. The sputum is also reduced in quantity. Many patients declare that they feel stronger in spite of loss of weight. Last but not least, it has a great psychological effect on the patient who thinks that something serious is being done for him.

From what has been said above it will be noticed that sanocrysin, like tuberculin, is a double-edged weapon which may cause more harm than good if not properly used. The treatment necessitates the daily examination of the urine, frequent taking of the temperature—in short, the close observation of the patient by the doctor. Sanocrysin is, therefore, a drug that is best suited for use in an institution where a well-trained staff is always available to meet the emergencies of the treatment. The patient must be intelligent and able to understand that he may have severe reactions and lose weight during the course. "It may also be necessary for him to go to a hill station for an after-cure."

It has been proved beyond doubt that sanocrysin cannot bring about complete sterilisation of the patient. Even Moellgaard did not claim a complete cure by its use. The best that can be said in its favour at present is, to use the cautious language of Lyle Cummins, that "sanocrysin carefully used in suitable cases is capable of leading to the temporary arrest of the disease and to a marked improvement in general health." In fact, it is argued by some that the cases which do well by its use, may be of "such a nature that one is inclined to think they would have done quite as well without any drug treatment under the simple influence of the old rest-and-air cure, the beneficial effects of which one is always too prone to forget."

It must be admitted at any rate that sanocrysin as a chemo-therapeutic remedy against tuberculosis can in no way be compared to salvarsan in the treatment of syphilis, as some enthusiasts seem to do. The latter has rapidly and unquestionably proved its curative power in syphilis. Of the former one cannot conscientiously say so.

MEDICAL EDUCATION.*

By E. W. C. BRADFIELD, M.S., F.R.C.S.,

LIEUT.-COL., I.M.S.,

Professor of Surgery, Madras.

THE problems of medical education are too extensive for a short paper, but in recent years so many changes have taken place, even altering the whole outlook of the medical profession, that an attempt to consider its position in this country and to define our aim and ideals is fully justified. The best methods of instruction in medicine have been the subject for consideration by a Royal Commission in England, and we ourselves have only just received a report on Indian medical colleges, which has severely condemned our shortcomings and drawn attention to the inefficiency of many of our methods. Numerous articles and papers too have appeared in medical journals, and the writings of Sir George Newman(1) and Mr. Abraham Flexner(2) are specially valuable to those who would study the subject. The true aim of a medical education, the need for training a doctor with a really scientific outlook and for the close co-operation of teaching with research, are not sufficiently realised in this country, where well-informed doctors are necessary for so many of the reforms which are now demanded. "Such public questions" says Sir George Newman "as the care of maternity, infant and child welfare, healthy adolescence, industrial hygiene, national physical efficiency and capacity and the avoidance of disease and premature death, find their answer ultimately in the progress and science of medicine, in the extension of its healing art, and in the soundness and completeness of the equipment of its practitioners."

Although the Madras Medical College was established in 1835 and a medical faculty created in 1857, the desire for cheap doctors has always influenced our educational policy. In this Presidency to-day, while there are 600 students receiving a university education at two medical colleges, 690 men and 134 women are taking at 7 medical schools the short four-year course to qualify themselves for the Government diploma. Last year 47 students qualified for the M.B., B.S. degree, 54 students for the L.M.S. degree, and 174 obtained the L.M.P. qualification. The inferior trained doctors have always outnumbered the university graduates and a reference to the Medical Register will show that the last twenty years' over-production of L.M.P.'s has resulted in a general overcrowding in the towns. It has not provided doctors for the village population. There are to-day 629 doctors practising in Madras town or roughly one doctor for every 840 people, a higher proportion than in the British Isles, where there is one doctor to 920. Other towns, e.g., Vizagapatam 68, Tanjore 43, also show large numbers of doctors and these figures take no account of the many practitioners of other systems of medicine. The majority of these registered practitioners have only the L.M.P. qualification and it is especially important that they should have had an efficient education and be able to sustain the ideals of modern medical science.

I am not concerned here with the unequal distribution of doctors. My contention is that the policy of our medical schools, which were designed first to provide a superior grade of Hospital Assistant and then extended to provide a lower grade cheap practitioner for the scattered districts, has failed. Village practice exhibits peculiar disadvantages in India and is as unattractive to the L.M.P. as to the University graduate. Over-production of cheaply made doctors cannot force distribution of cheaply made doctors and both prefer to concentrate in the towns where financial prospects are brighter. Personality, however poorly equipped, can always satisfy a public who prefer a mixture to be given with due mystery and appropriate rite for

every ailment, but such service does not satisfy the ideals of modern scientific medicine. I do not wish to depreciate at all what hospital assistants, sub-assistant surgeons and licensed medical practitioners have done as medical practitioners; their own Associations realise and are continually pointing out how handicapped they are by their inferior training. I know many who are the equals of our university graduates, but their success has been in spite of their medical school education and not as a result of it. What is called for is one standard of medical education to which all must attain. "Doubtless some will subsequently proceed to more numerous degrees and qualifications than others, and with greater gifts will produce greater results; but all doctors should be given a minimum comprehensive training based on scientific inspiration."

If we accept this finding and are prepared to advocate improvements in our system, we must have a clear vision of what we are leading to, because medical education is a serious and costly venture, and those who finance our educational schemes must be convinced that our ideals are right and the results to be attained worth the price that must be paid. In discussing therefore the problem of medical education I would first attempt to define our aim, then to discuss the basis of preliminary education on which we must work and finally to review the methods which characterise instruction in this and other countries.

The Aim of Medical Education.

In order to define our aims it is necessary that we should understand what manner of thing modern medicine is and the responsibilities which are to-day undertaken by the modern practitioner. Few of us can deny that at times our thoughts and actions yield to the spell of mysticism, perhaps the guiding principle in Chinese and certain indigenous systems. Superstition, however, has no place in modern medicine, while empiricism, an art which taught our forefathers the value of certain remedies and laid down rules of treatment, has yielded to scientific observation which has defined its limits.

If strictly defined as knowledge capable of quantitative expression, science would begin and end with mathematical physics, and most of our systems of knowledge would cease to be so called. Flexner, taking a historical and broader view, defines science as "the persistent efforts of men to purify, extend and organise their knowledge of the world in which they live. In this sense we are entitled to assume not only the science of mathematics and the science of physics, but also the science of biology, the science of agriculture and the science of medicine." The prevalent idea that a scientific education and outlook is dependent upon the part played by the laboratory is quite wrong. Science is essentially a state of the mind, a matter of observation, inference, verification, generalisation. The mind of the physician or surgeon occupied with a sick patient does not operate in any way differently from that of another scientist occupied with the results of an experiment in a laboratory. Both are using their power of observation, aided or not by special or delicate apparatus, both are assembling facts, interpreting and drawing conclusions. The main difference is that exact laboratory work is much simpler than ward work of anything like equal precision, but both the clinician and the laboratory worker are essentially scientific. "The clinic is not saved to science by laboratory methods; it includes them as simply additional weapons with which to do better, what scientific clinicians have always done, namely observe, explore, unravel."

Agreeing with this definition of medicine, what manner of man do we expect in the present-day doctor, who is a very different being from the private practitioner of pre-Lister days? The overwhelming importance of public health has added responsibilities in connection with the prevention of disease which are the inspiration of our profession. They have entirely changed the scope of the modern doctor, so that to-day the public and the State, which need competent

* A paper read before the South Indian Branch of the British Medical Association.

medical guidance, are deeply concerned with medical education and require that it should be free from quackery and incompetence. Sir George Newman in his note on medical education in England says, we require "a man of learning and knowledge in his vocation, with technical skill and medical experience; but above all a practical man with ideas and application, with a forward looking mind, able to participate in the growth and development of medical science, trained in the scientific method and inspired by the scientific spirit; in other words a man of accurate observation, of ability in experimentation and of sound judgment and interpretation." What kind of education will produce such a practitioner? "The answer to the question is complex, in a word it is university education in medicine, and the foundation of such an education is science."

Such is our aim in medical education, remembering that the function of a university education is not only to provide special technical instruction, but also to so expand the mind of the student that it may become a more perfect instrument of knowledge and progress. He must not only acquire a knowledge of those numerous facts which are necessary for the practice of his profession but his mind must be so trained that it can expand beyond the boundaries of old knowledge."

The Preliminary Sciences.

The basis or foundation of our education is science, considered as the preliminary scientific studies, chemistry, physics, and biology followed by the fundamental medical sciences, anatomy, physiology and pharmacology. The preliminary sciences are important. They afford an early discipline, the teaching of the scientific method, and they provide also the elementary data upon which the fundamental medical sciences are constructed. It is important that they should always be taught by experts, men who devote their whole time to teaching and research in these subjects, for it is here that the student is brought in contact with pure science and should learn that medicine is not a subject apart but is closely connected with advances in pure scientific knowledge. As is perhaps only natural, the expert often forgets that the medical student does not intend to become a botanist, a zoologist or a chemist and can only acquire knowledge of a small part of these vast subjects. It should be possible however to limit instruction and at the same time to give the insight into these subjects which is so necessary. The demands of the chemist especially appear to be growing more and more burdensome to the medical student, while instruction in biology is so often dominated by the type system that the student may learn little of the principles of comparative anatomy and of the laws of this important subject.

Medical College Organisation.

Medical colleges in India have grown up out of our hospitals, which originally undertook to train assistants for the medical services of the Government. The college itself at first granted diplomas, and it was not until some years later that a medical faculty of the university was formed. In this way we followed the British tradition, an example of Flexner's clinical type of medical school, as distinct from the university type which originated and grew up as part of the university in Germany, Scandinavia, Holland and many other European countries.

The clinical type of medical education, concerned mainly with the training of practical doctors, has grown up in England and France. You are probably familiar with the old British apprentice system. The young apprentice learnt his anatomy, the only exact subject of his curriculum in one of the special dissecting schools, and spent the rest of his training following his master from patient to patient. In course of time doctors in the various hospitals amalgamated and formed schools which undertook the training of students. At first and mainly from lack of funds, the

preliminary sciences were taught by clinicians, generally the juniors waiting for promotion. Later, with increased development of these fundamental sciences, came amalgamation with the university and this part of medical education was put on a sounder footing, the most important consideration being provision of whole-time teachers devoted to and experts in their subjects. Of recent years, the British Government has shown its concern in the maintenance of the quality of the profession and the Research Council, working under the Privy Council, has helped to support research workers and laboratories. There has been in fact a great movement towards a more scientific conception of medicine, and perhaps the greatest advance has been to place the clinical subjects on the same footing as the fundamental medical sciences.

The university type of medical education has been evolved in countries like Germany, Holland, Scandinavia, Denmark and others. The German university of the early 19th century emphasised research as well as teaching. The Professor of Medicine was in an exactly similar position to the Professor of Theology or of Greek, "not simply a teacher communicating a technique to successive groups of students, who in due course become practitioners of medicine. He was a master impregnated with scientific ideals, who surrounded himself with devoted disciples, serving long years as students or assistants on incomes hardly enough to sustain life." The whole system with its fully equipped institutions, clinical or laboratory, has always been well organised. The Professor is the pensionable servant of a State which controls education, while his assistants generally wait years for promotion, which results largely from original work in one of the medical sciences.

The clinical system has been essentially suitable for the British race and has produced a type of doctors second to none in the world. It has produced famous individual research workers such as Harvey, Hunter, and Lister in England. Claude-Bernard and others in France, but the outlook of the general practitioner in these countries has probably not been sufficiently scientific. The forward-looking mind demanded by Newman has often been absent, while the amount of research work turned out by their schools has been in no way equal to that of the better organised continental university systems.

These two systems have been very carefully analysed by Americans with their peculiar genius for organisation. Realising the value of the clinical system, which was the type of education originally prevalent in the New World, they have in many ways either completely changed the system or grafted on to it the better elements of the university organisation. One of the main stumbling blocks to better medical education has been the policy of honorary or unpaid clinicians, which to any degree has only existed in England and America.

It is difficult to convert honorary appointments, which are necessary in philanthropic institutions on account of expense, into paid university professorships, but this is now being done in all the more important centres in America, while in England the problem has been solved by the special institution of clinical units, in which clinical professorships are paid hospital appointments controlled by the university. In some American universities professors who draw their salaries from the university see private patients in order to gain requisite experience, but all fees are paid to the hospital and not to the professor. In other universities, where it has been difficult to institute rigid rules, various expedients have been designed and the whole situation is well worth consideration and study at a time when there is a political demand in this country for the appointment of honorary doctors to the hospitals.

Methods of Teaching.

A medical school cannot be expected to produce fully trained doctors. It can at the most only hope to equip students with a limited amount of knowledge and

endeavour to train them in the methods and spirit of scientific medicine, so that "they may be launched from the college with a momentum, which will make them active learners and thinkers for years to come." It is well to remember that medical education at the best can only be fragmentary, and that it is far better that the student should be given a full knowledge in a few subjects than an elementary or superficial knowledge of many. There is a great danger at the present time of over-loading the curriculum with too many specialities, undoubtedly necessary for the purpose of research and possibly also for the treatment of patients, but it must be insisted upon that the medical curriculum is not the place for the finished training of otologists, laryngologists and ophthalmologists. It is well also to remember that students should come to college to learn and not to be taught. Good teaching is not over-elaboration but guidance, while "a medical student who requires to be controlled from day to day or hour to hour has probably mistaken his calling."

The guiding principle of British medical education is what is known as "the block system" which insists that a student must complete his training in the preliminary and fundamental sciences before proceeding to the clinical part of his curriculum. It is desired that the student should first have a clear conception of the body in health, before any study of disease is undertaken. Perhaps it is a weak point that there is little or no special provision for honours students in most of the schools, the aim of all being to train a man as a practical doctor and after that permit him to become an expert or a specialist. In some continental schools, in France especially, there is a good deal of over-lapping of the clinics and sciences, while in others, although students are allowed very considerable freedom in the choice of classes which they can attend, their time is perhaps too much occupied with listening to and watching their teachers. They often do very little assisting and have little or no responsibility given to them. Active participation in the work of the clinic or laboratory is the strong point of British medical education.

In general it can be said there are three methods of teaching, the systematic lecture, the demonstration, and practical exercises. The systematic lecture varies enormously with the teacher and its success depends largely on his personality. The minds of students who attend too many lectures soon reach a saturation point and the modern tendency is more and more to limit this kind of instruction. No student can be really taught by continuous repetition, and the Tamil proverb, which states that "if you continually beat a stone, it will eventually move" is in no sense applicable to a scientific education. Those who befriend the dull student I would refer to another Indian proverb: "You may put a dog's tail in splints for 20 years but it will not grow straight." Demonstration is a far better method, especially when it is given to small groups of students. The tendency closely connected with our high admission rates to hold classes for a very large number of students is entirely to be condemned. Active participation of the student in practical exercises should be the main instrument in our scheme of teaching, and one in which we should encourage initiative and not over-do supervision. At some of our Indian institutions the student takes part in very few practical classes and it is quite possible at a final examination to find candidates able to recognise a slide under the microscope, without knowing how the slide was prepared and how to adjust the instrument.

The hospital ward is the laboratory of the clinical teacher who should be guided by the same scientific principles as his colleagues in the preliminary and fundamental sciences. In England the foundation of clinical units has introduced a special organisation intended to provide education of a university standard and to facilitate research in the clinical subjects. It

has acknowledged the failure of the honorary medical officer as a teacher, and has recognised the necessity of providing paid teachers in all the medical sciences, clinical as well as pre-clinical, men who can devote all their energies to the training of medical students and the advancement of clinical medicine. The student during his clinical course holds various appointments as clerk or dresser, where he becomes part of the hospital machine. He is an intelligent apprentice and is given definite responsibilities. The value of this part of his course lies in his own study of individual patients under guidance and control rather than in listening to the explanations of his teacher, while all the time he should be made conscious of the scientific efforts going on around him. Discussion and demonstrations are valuable adjuncts, but the systematic lecture is becoming less popular, and at most institutions attendance at such classes is voluntary.

Indian education as a whole, both school and college, is too much dominated by examinations. No other satisfactory system has, it is true, yet been invented which can replace this method of testing a student's knowledge, but its importance should not be over-emphasised. Examinations should be subsidiary to education and should not attempt to lead it. It is a well-known fact that the sudden announcement of an examination is the surest way of clearing our hospital and laboratories of students, whose minds are obsessed by the coming test and with whom the latest cram book or synopsis is far too popular. Most examinations are unsatisfactory, but probably the majority of examiners are reasonable sensible beings whose purpose it is to find out how much a student knows, and endeavour to put questions which will discover the extent of a student's knowledge. There are examinations, however, within our knowledge in which far too large a percentage of failure occurs and to which we ought to pay very careful attention. The fault probably lies with the size of our classes, for to inspire a class of 100 students—an average number—with scientific ideals and at the same time supervise their practical teaching is beyond the powers of our limited teaching staffs.

Research and Education.

Research to-day is an important part of medical education. The Royal Commission on University Education in London in 1913 reported "It is a necessary condition of the work of university teachers that they should be systematically engaged in research work." The spirit of investigation has always been vigorous in Western medicine; at first it was able to utilise methods of observation only, then with the invention of instruments of precision experimentation was added, and during the past decade the laboratory has so rapidly increased our knowledge that clinical research has often found it difficult to keep pace with its discoveries. In Germany and many other continental schools, research has for many years been accepted as one of the essential duties of the medical teacher, while in Britain this principle has been acknowledged in all recent university legislation. In India education and research have generally been kept apart, out of touch with each other, and their separation into separate departments has been unfortunate for both. On the one hand the research worker, often segregated on a hill-top, has been out of touch with disease, and except when engaged in a very special investigation, too academic in his ideas, which require co-ordinating with those of the clinician. The educationist on the other hand has too often passively allowed research to remain in a water-tight compartment, while his own teaching has been without imagination and his subject presented to the student as a mass of dry facts. I would again urge that there is "no greater mistake than the assumption that research 'spells' only labour with test tubes, Petri dishes, serums and guinea-pigs." The ideals and methods of both the clinician and the laboratory worker are essentially the same; both are

continually using their powers of observation, analysis, deduction and description. Your true doctor spends his life in pursuing methods of experimentation, increasing his own store of knowledge, and sometimes adding to that of others. The only difference between the two workers is that exact laboratory work is much simpler than ward work of anything like equal precision, so that the latter often fails to keep pace with the advanced ideas of the laboratory worker. Both are inspired by the spirit of discovery and the "scientist at work in his laboratory can never reap the full reward of his lonely researches without close and loyal collaboration with the clinicians." I would here protest against the practice, which appears to be growing in India, of calling institutes, generally privately owned, whose only function appears to be the carrying out of routine tests on blood, urine and other pathological fluids for busy medical practitioners—"research institutes." They undoubtedly supply a want and are in many ways valuable, but they do no original work and that they should be allowed to make such a misuse of the word "research" is deplorable.

It was a little disappointing on reading the long report of the General Medical Council's commission to find that so little has been said on the subject of research, though perhaps it was right to concentrate on many shortcomings in the way of buildings, supply of teachers and other matters, which are so obvious and yet so difficult to convince a Government of. In India the student suffers from many disadvantages, and his early training at home, at school, and at an Arts college is all against the development of scientific thought. Surely if we are to produce the forward-looking medical practitioner it is necessary that the medical student from his earliest days should be steeped in a method of critical investigation. He should not be taught a mass of hard facts, but rather be made to realise the amount of investigation that is going on and to see these methods daily being undertaken by his teachers. Until the necessity for research is put in the forefront of our scheme of medical education, we can never hope that Indian practitioners will attain a high place in the medical world.

In conclusion I would again emphasise that, revived by the work of Pasteur and Lister and influenced by the responsibilities in public health which the profession has freely undertaken, medicine has during the life-time of some of us obtained a new outlook—"A new birth." (3) The President of the Royal College of Surgeons has delightfully summed up the position as the new approach to surgery. (4) "But all my life," he says, "I have wished that my training had been different. Were my days to come again I should, after leaving examinations behind, spend the time necessary to make an adequate knowledge of human anatomy my permanent possession, and should then escape to experimental research and, in a community of like-minded people endeavour to train myself for the high destiny of a surgeon, the one man who may engage in direct research. My time would be spent in the laboratory, where a youth of plastic mind may learn the methods of approach to new problems or to new extensions of old problems; where old knowledge is merely an impulse to the search for new; where intellectual dissatisfaction is victor over narrow complacencies; where the religion of research inspires him and equips him for his work in days to come. If surgery is to be something more than a wonderful craft, if it is to be the instrument of research which I believe it to have been, and to be destined to be in the future, those who practise it must have their minds shaped and strengthened by conflict with unsettled problems, not cramped and sterilised by monotonous exercise within a narrow province of static knowledge. Their minds must be trained in the laboratory and in analogical research, so that they may be more effectively exercised both in the operation theatre and in the wards upon direct research. . . . The training of the surgeon must not only allow, it must urge his mind

to stray beyond the hard boundaries of old knowledge, over the edge of firm beliefs, into wide territories as yet unexplored and even undivined. In this way only is there escape from the danger which besets the surgeon in the future, the peril of a facile automatism."

Current Topics.

India and the League of Nations.

AN interesting and novel departure is the study tour interchange of public health officers, which is at present touring India under the auspices of the League of Nations. The purpose of these study tours or "interchanges," which were first started in 1922 with the help of a grant from the Rockefeller Foundation, is not only to enable the medical officers taking part in the tours to benefit by the technical knowledge gained, but also to establish personal contact and understanding between public health workers in different countries. The objects of the present tour are "to study the organisation of the medical services in India, its statistical services and medical institutes; the work done for the control of epidemic diseases, notably malaria, plague, cholera, small-pox, kala-azar, rural sanitation and drinking water supplies, public health measures at fairs, etc.; medical research work, the army health service, and the diseases which are special to India." The members participating in the tour are as follows:—

Australia.—Dr. A. H. Baldwin, Australian Institute of Tropical Medicine.

Ceylon.—Dr. Chellappah, Colombo.

Dutch Indies.—Dr. Ch. Winckel, Weltevreden.

Federated Malay States.—Dr. A. R. Wellington, Chief Health Officer, Kuala Lumpur.

Indo-China.—Dr. P. Hermant (Annam) and Dr. E. Jourdan (Tonkin).

Japan.—Dr. Tsunetare Fukuda (Kanagawa) and Dr. S. Nishiki (Korea).

New Zealand.—Dr. T. Hughes (Auckland).

Philippine Islands.—Surgeon C. R. Eskey (Manila).

Siam.—Dr. Luang Chedt (Bangkok).

Straits Settlements.—Dr. A. L. Hoops, Principal Civil Medical Officer, Singapore.

The "interchange" met first at Delhi on January 1st in order to hear a general account of the problems which are to be studied, and to be given an insight into the working of the Indian medical services from headquarters; also to be shown the work of the Central Malaria Organisation. The further programme is as follows:—

Jan. 3rd to 9th. Lahore.

Jan. 10th to 16th. Lucknow and the United Provinces.

Jan. 16th to 18th. Patna and *en route* to Calcutta.
 Jan. 18th to 24th. Calcutta.
 Jan. 25th to 30th. Shillong and Assam.
 Jan. 31st to Feb. 7th. Madras.
 Feb. 8th to 10th. Mysore (probably).
 Feb. 11th to 18th. Bombay.

Interchanges, like other League activities, began in Europe, but as regards at any rate the Health Organisation, the League has long ceased to be merely European and has become world-wide, and in nothing has this been shown more clearly than in the system of interchanges, which have been held in North and South America, in Africa and Japan, as well as in Europe, and included participants from the health services of practically every country in the world, whether a member of the League or not.

In general, an "interchange" or study tour consists of a period devoted to studying documents and hearing lectures, followed by visits and knowledge gained on the spot from those actually engaged in some line of health work, and concluding with a final conference of two to three days, during which the participants present reports and discuss with the organisers of the interchange and each other what they have learned during the whole period. Experience has shown that these interchanges are of advantage not only to the health administrations which send participants but also to those of the countries in which interchanges are held, owing to the exchange of views and experience, and the necessity for a health service acting as host to explain itself and its works to the foreign guests—it is notorious that one of the best ways to learn a subject is to teach it to others.

In other directions too the Health Organisation is thoroughly cosmopolitan, such as in its world epidemiological intelligence service, for which the centre in the Far East is Singapore, and by which all Far Eastern port health authorities, including those of India, benefit directly. India indeed has taken an active part in the development of the work of the League epidemiological intelligence office at Singapore, and is represented on the Advisory Council of this body as well as on the Central Health Committee at Geneva.

The Malaria Commission too of the League Health Committee has already studied the question of the best and most economical methods of combating malaria, not only in Europe but in North Africa and the United States, and has just accepted the Indian Government's invitation to extend its studies to India.

Research work has been begun by the Health Committee on the advice of its Far Eastern Advisory Council on plague and methods of oral vaccination against cholera, with which India is directly concerned and in which Indian medical officers are co-operating.

The Lady Irwin Gold Medal.

We have been asked by the President of the Central Social Service League, Delhi, to state that the Lady Irwin Gold Medal for the study of Tuberculosis has been awarded for 1927 to K. L. Basu Mullick, M.B., Chackasi, Howrah District, for his essay entitled "The Prevention of Pulmonary Tuberculosis among Purdah Women in the large towns of India." A large number of interesting essays were sent in.

The Army in India Reserve of Officers, Medical Department.

We have been asked by the D. A. A. G., Presidency and Assam District, to bring to the notice of European

and Indian civil medical officers with the requisite qualifications the fact that a considerable number of vacancies still exist for officers in the Medical Department of the Army in India Reserve of Officers. Details with regard to these appointments are furnished in the *Regulations for the Army in India Reserve of Officers*, published by the Central Publication Branch of the Government of India, Calcutta, 1927, at 4 annas. From that publication we abstract the following information:

The personnel of the Army in India Reserve of Officers consists of two classes; "officers" and "officers designate." The former are on the permanent cadre; the latter are members of the Auxiliary Force, India, whose names have been registered for the grant of a commission in the Army in India Reserve of Officers upon the calling up to army service of that reserve. On general mobilisation of all military forces in India being ordered, all officers and officers designate of the Army in India Reserve of Officers will be liable to be called to army service. Notification will be by *Gazette* notification, but also each individual called upon will be individually notified. If only partial mobilisation be ordered, officers and officers designate will be invited to volunteer according to the condition of emergency existing.

Applicants for the Medical Department must possess a qualification registrable by the General Medical Council of Great Britain under the Medical Acts in force at the time of their appointment. On first appointment such medical officers will be given the rank of lieutenant; to become captain at the end of three years of service, and major at the end of twelve years' service; promotion to lieutenant-colonel depending on selection. Officers who held King's commissions between the period 4th August 1914 and 11th November 1918 will be entitled to count double such period of commissioned service for purposes of seniority for promotion, etc. Other previous King's commissioned service in any branch of His Majesty's British, Indian or Dominion, naval, military, or air forces will count in full. Service as a warrant or non-commissioned officer or private will count as half commissioned service under similar rulings.

Every applicant will be required to produce evidence from his employers or other "superior authority" in civil life that his services can be spared when necessary. Applications should be made ordinarily to the headquarters of the district or independent brigade in which the applicant's normal residence is located; e.g., in Calcutta or Bengal or Assam to the D. A. A. G., Presidency and Assam District, Calcutta. Candidates for employment in the Medical Department of the Army in India Reserve of Officers will require to be approved of by the Director of Medical Service of Army Headquarters before acceptance. Each applicant will be medically examined as to his fitness for service before being enrolled.

Officers appointed will undergo 16 days' training every alternate year, but such period of training may be extended to 30 days in any one year for individuals who desire to undergo this special course. Arrangements may be made to send such officers—under the usual travelling and similar allowances—for training to the North-West Frontier area. For officers who happen to be in Great Britain at the time, arrangements may be made for their training to be carried out with British units at Home.

In time of peace, every officer or officer delegate of the Reserve will receive a retaining fee of Rs. 200 per annum, payable in arrears in January of each year. A certain outfit must be maintained, for which an initial allowance of Rs. 400 is allowed, on production of a certificate that this is in the officer's possession. On mobilisation and call to army service, officers of the Medical Department will draw pay at current I.M.S. rates. These are as follows, as laid down in Appendix "C" of the regulations.

APPENDIX "C."

Officers and officers designate of category (II).
(I. M. S. Rates.)

Rank.	Service in rank.	Basic pay.	Overseas pay drawn in rupees.	Year of total service.
Lieutenant	500	150	1
			150	2
			150	3
Captain ..	(i) During first 3 years' service as Captain.	650	150	4
			150	5
	(ii) With more than 3 and less than 6 years' service as Captain.	750	150	6
			250	7
			250	8
			250	9
	(iii) With more than 6 years' service as Captain.	850	250	10
			250	11
			300	12 and over.
Major ..	(i) During first 3 years' service as Major.	950	300	
			300	
			300	
	(ii) With more than 3 and less than 6 years' service as Major.	1,100	300	
			300	
			300	
	(iii) With more than 6 years' service as Major.	1,250	300	
			300	
			300	
Lieutenant-Colonel.	(i) Until completion of 23 years' total service.	1,500	300	
			300	
			300	
	(ii) During 24th and 25th year's service.	1,600	300	
			300	
			300	
	(iii) After completion of 25 years' total service.	1,700	300	
			300	
			300	
	(iv) When selected for increased pay ..	1,850	300	
			300	
			300	

With regard to leave passages for officers and families when the former are called to duty, pensions and gratuities, the rules in general follow those for the regular military services. Every officer and officer designate is required to report his address through the headquarters of the district or independent brigade concerned in January each year. The distribution of these districts and brigades is as follows:—

Peshawar District, Peshawar	Northern Command.
Kohat District, Kohat	
Rawalpindi District, Rawalpindi	
Lahore District, Lahore	
Waziristan District, Dera Ismail Khan	
Poona District, Poona	Southern Command.
Central Provinces District, Mhow	
Bombay District, Bombay	
Madras District, Bangalore	
United Provinces District, Meerut	
Presidency and Assam District, Calcutta	Eastern Command.
Allahabad Brigade Area, Allahabad	
Delhi Brigade Area, Delhi	
Baluchistan District, Quetta	Western Command.
Sind-Rajputana District, Karachi	
Zhob Independent Brigade Area, Loralai	
Burma Independent District, Maymyo.	
Aden Independent Brigade, Aden.	

Officers and officers designate when going on leave are also required to notify the Military Secretary, Army Headquarters, Simla, through the headquarters of their district or brigade area concerned, that they are doing so.

India has at present no organisation corresponding to the R. A. M. C. (Territorial) Force which rendered such magnificent service during the Great War. On the other hand there are innumerable medical men in India, both European and British, who are eligible for the Army in India Reserve of Officers, Medical Department. On a study of the regulations, we would point out that the essential duties involved are not onerous; to keep up a certain small kit and equipment; and to undergo 16 days' training every alternate year. Officers will not be called to the colours unless general all-India mobilisation is enforced; under partial mobilisation only volunteers will be called for. If called to the colours in the event of war, the rates of pay and allowances are in general those of the Indian Medical Service. We doubt whether any scheme which involves less commitment on the part of those enlisting with more generous recognition of their services could possibly be devised for this country. During the Great War, one fact with regard to India became very obvious; that was that the Indian Medical Service, which first became an all-India service in 1913,—with a general all-India roster,—despite its immense services to the country and to the Empire during the war, had no general reserve. Those previously in civil employment were very rapidly absorbed into the fighting services; indeed some provinces were more than stripped bare of civil surgeons, professors, and specialists. There were hardly any to take their place.

In the event of some future war, there should be some reserve of trained medical officers. This want the Medical Department of the Army in India Reserve of Officers attempts to fill. We trust that we may appeal to those of our readers who possess the necessary qualifications to come forward and "join up." The time when the sky is clearest is the time to make provision for a "rainy day"; a future war may be incredible, but should it come, we do not desire to see repeated again the lack of personnel of 1914-15 in Mesopotamia.

Medicine and the Church.

By SIR FARQUHAR BUZZARD, K.C.V.O. M.D. (Ox.)
F.R.C.P. (Lond.).

Abstracted from the *Lancet*, November 12th, 1927,
p. 1006.

In Egypt 3,500 years before Christ with the earliest indications of the art of medicine, the art at that time was concerned only with treatment. It was practised by men who combined the offices of priest and physician and who regarded the invocation of blessings on their remedies as not the least important security for their success.

The early records of both Indian and Persian medicine emphasise their close association with religion, and suggest that sickness and recovery therefrom were attributable to the influence respectively of hostile and friendly deities.

In Greece were laid the real foundations of rational medicine, and it was left to Hippocrates, a direct descendant of Aesculapius, to develop from the prevailing methods and doctrines of his day a new outlook upon the origin and treatment of disease, which has caused him to be regarded as the greatest physician of antiquity.

To him the conditions of health and sickness were determined by seasons, climates, waters, and soils, as well as by personal habits in such matters as food and exercise. His pathological conceptions were not so happy. Four humours of the body—blood, phlegm, yellow bile, and black bile—were, according to his theory, the primary seats of disease, and health varied in relation to disturbances in their proper combination and appropriate activities. Not his least claim to

fame was his attitude of expectancy in regard to treatment. In fact his aversion to drastic remedies earned him the reproach of letting his patients die by doing nothing to keep them alive—a reproach which has lost some of its sting with the advance of knowledge.

Galen, born at Pergamus in A.D. 131, was destined to influence the progress or perhaps it would be more correct to say, the stagnation of medicine for from 12 to 15 centuries. As an expositor of the medical knowledge of his time, as an anatomist and skilled dissector of the bodies of lower animals, and as a practical physician his reputation must always stand pre-eminent. As a physiologist and pathologist his contributions were of less value, and his dogmatism in regard to these subjects, fostered by the atmosphere of infallibility which pervaded both medicine and the Church for so many centuries, was a standing menace to all progress during the whole of that time. Galen's doctrine did not come into its full power until his writings, having been translated into Latin, began to be studied in the West, with the result that by the sixth or seventh century his name and authority began to dominate medicine and thereafter kept it in chains for another thousand years.

From the early Middle Ages the religious orders were the custodians of the degenerate knowledge and practice of the healing art inherited from the later Roman authors until the curious mixture of ancient science with the black art, characteristic of monastic medicine, was superseded by the Hippocratico-Galenic revival. The latter doctrine survived until the medical reformation, which took place very little later than that of the Church and which is so closely associated with the name of Vesalius, the founder of modern anatomy, who was condemned by the Inquisition as a sorcerer, and with that of William Harvey, the father of modern physiology. But those who took part in the reformation of medicine were not only exposed to the persecution of the Church, but were bitterly opposed by the disciples of Galen, and Vesalius himself did not escape the hostility of the latter when he published his monumental work on human anatomy in 1543.

The Church during the Middle Ages exerted its influence to uphold the Galenic doctrine, which presented no inconsistencies with the Christian faith and which dogmatically provided an answer to every question. Comment was allowed and commentators abounded. Criticism, on the other hand, was looked upon as a species of heresy and critics shared the fate of religious heretics. Research and experiment were regarded as closely akin to sorcery and witchcraft.

But medicine owes the Church a debt of gratitude for the performance of at least two valuable functions during the dark years of its history. The monastic orders were responsible for preserving the ancient literature of our profession which would otherwise have been lost, and they were pioneers in the establishment of hospitals which eventually formed the basis of many famous and productive medical schools.

Dr. Arnold Chaplin writes:—

"In early times, before the foundation of the Universities, the art of Medicine was largely the province of the Church, but in 1131, the Council of Rheims prohibited the regular clergy from devoting their attention to physical conditions, and after this edict the regular clergy confined themselves to prescribing medicines. In 1139, the Council of the Lateran prohibited physicians from administering to the wants of the body before the spiritual needs of the patient had received attention.....In 1422 the first enactment concerning the practice of medicine appears upon the statute book. "No one shall use the mysteries of fisyk, unless he hath studied it in some University and is at least a bachelor in the science. The Sheriff shall enquire whether any one practice in this country contrary to this regulation; and if any one so practice he shall forfeit £40 and be imprisoned." The Church, however, still continued to exercise some authority, for in a statute of 1511 it is stated that "except for those

graduating in Medicine at Oxford and Cambridge, all desiring to practise medicine or surgery in London and seven miles around must be approved, after examination, by the Bishop of London or the Dean of St. Paul's with, in the case of Physicians, the assistance of four doctors in physick, and, in the case of surgeons, of other expert persons of that faculty."

It is interesting to trace the gradual development of a new attitude towards research. Thus the secrets of Nature came no longer to be regarded as sacred and knowable only to the Almighty, when difficulties were encountered in the attempt to unravel them. There arose, on the contrary, a spirit of inquiry undeterred by obstacles and no longer trammelled by the belief that the search after knowledge was incompatible with the Christian faith. For example.

Vesalius (1514—1564).—"The septum of the Ventricle abounds on both sides with little pits impressed in it. Of these pits, none, so far at least as can be perceived by the senses, penetrate through from the right to the left ventricle, so that we are driven to wonder at the handiwork of the Almighty, by means of which the blood sweats from the right into the left ventricle, through passages which escape human vision."

Harvey (1578—1657).—"When I first gave my mind to vivisections, as a means of discovering the motions and uses of the heart, and sought to discover these from actual inspection and not from the writings of others, I found the task so truly arduous, so full of difficulties, that I was almost tempted to think, with Frascatorius, that the motion of the heart was only to be comprehended by God. At length, and by using greater and daily diligence, having frequent recourse to vivisections, employing a variety of animals for the purpose, and collecting numerous observations, I thought that I had attained the truth."

At the time when Harvey was engaged on his life's work, the result of which was to deliver from darkness into the light of truth the secret of the circulation of the blood, the Church found it desirable to forbid the clergy to attempt to cast out devils by fasting and prayer, except by special licence from the bishop. The tercentenary of the publication of Harvey's "De Motu Cordis," the monograph giving to the world his great discovery, is to be celebrated in a befitting manner in 1928.

Since his time the science of medicine has steadily progressed, partly as the result of untiring research at the bedside, in the post-mortem room, and in laboratories, and partly as the result of the rapid development of such ancillary sciences as those of physiology, anatomy, chemistry physics, biology, and bacteriology. Progress at first was slow, hampered by tradition, by prejudice, and by the very human mistake of regarding hypotheses as final conclusions instead of using them as a basis for research. In the last 100 years the wheels of progress have moved much more rapidly, and, our conception of medicine as a profession has completely altered since the days when the physician-priest of Egypt essayed blindly to cure the sick with a mixture of blessings and herbs.

For more than a thousand years, during which the Church shared the practice of medicine with physicians, and dominated its methods, during which she was at the height of her spiritual power, and during which millions of the sick and suffering must have passed through her hands, there was no material advance in the knowledge of disease, of its cure, or of its prevention. Moreover, from the records of those centuries in which the Church had every facility and every opportunity of proving her gifts, there has survived no evidence in support of the claim that spiritual healing of organic disease is a practical proposition, or that spiritual healing differed, either in its essence or its efficacy, from other methods based on suggestion and faith, religious or otherwise.

On the other hand, the last two or three hundred years have witnessed a gradual separation of the paths of medicine and of the Church, and synchronous with

that process the advances of medicine in regard to the diagnosis, treatment, and prevention of disease have only been equalled by the remarkable progress made in other branches of science which threw off the fetters of the Church about the time of the Reformation.

The weight of authority in the English Church is now against the claim to heal "organic" disease. Thus the Committee of the Ministry of Healing appointed by the Archbishop of Canterbury in 1920, say:—

"Our Committee has so far found no evidence of any case of healing which cannot be paralleled by similar cures wrought by psychotherapy without religion and by instances of spontaneous healing which often occur in the gravest cases in ordinary medical practice."

Sir Farquhar deals with the subject of Faith which says the writer of the Epistle to the Hebrews, "is the substance of things hoped for, the evidence of things not seen."

This definition is not lacking in beauty and simplicity of language or of conception, and it has the advantage of offering to us a meaning applicable alike to faith in God and faith in man.

The scientist cannot fail to recognise the reality of faith and the immense power for good and happiness which it exercises in the lives of a large proportion of the community.

The Pathology of Subtertian Malaria.

By DR. IAN MACKENZIE.

SOME very interesting observations on the pathology of subtertian malaria are recorded by Dr. Ian Mackenzie in the *Journal of Tropical Medicine and Hygiene* for August the 16th, 1927. These observations were collected in Sierra Leone, the West Indies, and Venezuela over a period of nine years; no less than 1,150 cases having been observed.

"Examination of the record cards bring out the following points:—

(1) Anæmia is marked and progressive during the first week of the attack, but as a rule recovery in new cases is prompt.

(2) The blood-pressure at some period of the paroxysm is lowered almost invariably. There is a marked relationship between a low blood-pressure and localization of symptoms.

(3) After a preliminary leucocytosis, leucopenia is the rule, and in the majority of the readmissions there is a relative and absolute increase in the large mononuclears.

(4) The coagulation time of the blood is sometimes increased, sometimes unaffected, and more rarely decreased.

(5) In the majority of the cases rigors are not marked.

(6) The temperature charts are very irregular in first attacks, but become more frankly intermittent in the relapses.

(7) The rate of hæmolysis is less marked in the relapse, although the anæmia is as a rule more profound.

(8) Where quinine prophylaxis (5 gr. daily) has been given, the clinical symptoms of an attack are often more intense, and the immediate reaction to quinine less effective than when no prophylaxis is employed. This is more noticeable in first attacks.

(9) The addition of iron and arsenic to the prophylactic quinine, although it did not materially decrease the number of admissions, diminishes the amount of anæmia associated with the attack.

(10) In areas where malaria-infected mosquitoes are numerous, quinine in 5-gr. doses is insufficient to prevent an attack. By doubling the daily dose the incidence is much reduced (40 per cent. less in one locality).

(11) Quinine treatment by the mouth, provided there is no vomiting, seems to be as efficacious as by any other route."

Turning to the old standing and much discussed question of the causation of relapses in malaria, the author concludes that the whole weight of evidence in his researches is against the view put forward by Schaudinn many years ago that relapses are due to the production of merozoites by parthenogenesis on the part of the macrogametocytes. He writes:—

"(1) Despite Karroway's observation that he found parthogenesis to occur in *P. vivax* at the height of the paroxysm, most careful examination of thousands of films and hanging-drop preparations in a large number of malarial cases has failed in every instance to show anything suggestive of retrogressive schizogony. When gametocytes existed in the peripheral circulation, a double infection of a corpuscle with a schizont and a gametocyte was not infrequently observed.

(2) Post-mortem examination of smears from the viscera—spleen, liver, brain, bone-marrow—in cases known to be free from the clinical manifestations of malaria for at least three months before death, but all of whom were chronic malaria subjects, showed the capillaries filled with blood containing parasites and leucocytes with pigment: the red cells of the splenic pulp contained schizonts and crescents.

(3) Provocative attacks of malaria were produced by the intravenous injection of adrenalin in three out of six cases whose peripheral circulation showed an excess of large mononuclears and pigmented leucocytes, but no plasmodia.

(4) Splenic puncture in ten cases with moderately enlarged spleens, in whom the clinical manifestations of malaria were absent, and crescents only could be found in peripheral blood, demonstrated the presence of sporulating forms in the films of six.

(5) A Syrian was admitted into hospital with amœbic dysentery. On examination, his blood was found to be swarming with crescents, and, in spite of prolonged examination of more than 100 films, no plasmodia could be discovered. There had been no clinical evidence of malaria for many months. By means of a Pravaz syringe, blood from this subject was injected directly into the basilic veins of five members of his family who lent themselves for the experiment in quantities of 1 c.c., 2 c.c., 4 c.c., 6 c.c. and 8 c.c. In no case did these injections produce an attack of malaria. Some time later, half a c.c. of blood containing plasmodia from a case of subtertian malaria was injected into this Syrian. Within ten days he was readmitted with a typical paroxysm, his blood swarming with plasmodia. Finally, half a c.c. of his blood, containing the plasmodia, was injected into the members of his family previously inoculated with crescents. Four out of the five developed an attack within two weeks.

While the series of experiments and observations described cannot be considered as conclusive evidence against parthenogenesis, I submit that they are sufficiently suggestive to make us hesitate before accepting Schaudinn's view.

Of the fact that quinine in sufficient dosage kills off the crescents in time, there can be no doubt. One series of cases, 100 natives, whose blood showed numerous crescents but no plasmodia, were given 30 grains of quinine a day with the following results:—

Shortest time required for the disappearance of crescents, five days; longest time for their disappearance, twenty-eight days; average time required, 17.5 days."

Blood Transfusion in Sprue.

By DR. G. C. LOW, M.D., F.R.C.P.

and

W. E. COOKE, F.R.C.S., (Ire.), D.P.H.

The Lancet, 5th November 1927, p. 960.

THE following are abstracts from this very interesting paper:—

In the later stage of sprue a blood picture very like that seen in pernicious anæmia often develops. This

hæmolytic type of the disease is very dangerous and often fatal.

A detailed account of the blood in such cases was given by one of us (G. C. L.) as long ago as 1912. It was there pointed out that in the later stages it might be practically impossible to differentiate the blood picture of sprue anæmia from that of true pernicious anæmia. On this picture some have argued a relationship between the two diseases, or even their identity, but sprue is a definite entity with a symptomatology and pathology of its own and is not pernicious anæmia.

Transfusions of whole blood have been used for some time in pernicious anæmia, septicæmia, loss of blood from hæmorrhage, often with very beneficial results, and recently a patient suffering from the hæmolytic type of sprue was transfused with whole blood just before coming to us. Under our treatment the sprue improved and he apparently completely recovered, but after leaving us and living at home for some time he relapsed and again developed a very severe type of anæmia. We therefore took him back into the Hospital for Tropical Diseases and, his wife being a suitable donor, her blood was used for the transfusion.

A Short Résumé of the Cases.

Case 1.—European male, aged 58. Residence abroad, India and Mesopotamia. Previous illnesses: enteric fever, 1888; dysentery, 1890 and 1895.

Sprue began in 1917. By 1923 the disease had so progressed that the patient was admitted to a general hospital in England, his blood count reading: red cells 600,000, hæmoglobin 22 per cent. Three whole blood transfusions performed during a period of 27 days resulted in a rise of the red cells to 800,000, hæmoglobin 27 per cent. Four months later the count read: red cells 1,460,000, hæmoglobin 56 per cent.

When transferred to the Hospital for Tropical Diseases, London, on April 10th, 1924, he was still very ill and wasted. Weight 6 st. 12 lb., and the blood count was red cells 2,440,000, hæmoglobin 65 per cent. With our usual line of treatment he improved so much that he was able to leave hospital on August 1st, 1924, his weight having risen to 11 st. 1 lb., and the count to red cells 4,160,000, hæmoglobin 80 per cent.

During the following two years the patient returned to hospital twice for short periods of treatment.

On July 7th, 1926, the blood count had fallen to red cells 3,000,000 and hæmoglobin 75 per cent.; poikilocytosis and nucleated red cells were present, but after readmission to hospital on that date the decline continued in spite of the usual methods of treatment, until August 6th, 1926, when it was decided to transfuse with blood in the hope of checking it. The count on that day was red cells 2,300,000 and hæmoglobin 65 per cent.

The wife acting as donor, 700 c.cm. of whole blood were given by the citrate method. No rigor occurred, but the transfusion was followed by a rise of temperature to 100°F. Three days later a further decline had taken place, the count reading red cells 2,000,000, hæmoglobin 65 per cent., and a trace of albumin was found in the urine. By September 7th following—that is, a month later—the red cells totalled 4,200,000 and hæmoglobin was 80 per cent., and the patient was discharged in the following week with a count of 4,700,000 red cells and 85 per cent. hæmoglobin, feeling much better in every way. He has reported at intervals since his discharge and was keeping well up to September, 1927.

An even more striking case is the following:—

Case 2.—Mr. X., an old case of sprue, who had never been very anæmic, went home to Scotland. Apparently he relapsed there and rapidly deteriorated, his blood count falling and his general condition becoming alarming. It was then decided, though the risk was considerable, to bring him to London, where he arrived on the morning of October 2nd, 1926.

Previous Illnesses.—Malaria and dysentery, 1888; syphilis and gonorrhœa, 1891; hepatitis, 1902; cholera, 1917. Ptomaine poisoning, 1919. Had lived in India and New Zealand.

Present Illness.—In 1920 diarrhœa began, with light-coloured stools, sore tongue, and loss of weight, the onset of sprue, so in 1921 he returned to England.

On December 8th, 1922, patient was admitted to the Hospital for Tropical Diseases, after seeing one of us, and he had to return to hospital on five subsequent occasions. On each of these he responded to treatment for the sprue with varying success, and when in hospital the specific infection was treated with potassium iodide, N.A.B., and bismuth. On May 20th, 1926, he was discharged from hospital to spend the summer in Scotland, his red cells numbering 4,500,000; hæmoglobin 85 per cent.; weight 13 st. 12 lb.

The following September (1926) he relapsed so rapidly that on October 1st the task of bringing him from Scotland to London was one of considerable difficulty and risk. For three days before the commencement of the journey he had been vomiting continuously and was only conscious at intervals.

On his arrival at the Hospital for Tropical Diseases at 8-45 a.m. on October 2nd in an unconscious condition, 10 oz. of 5 per cent. glucose saline solution were at once administered intravenously. The blood count on admission was: red cells 940,000, hæmoglobin 20 per cent. As no return to consciousness or marked improvement followed the glucose injection, it was decided to transfuse with whole blood, and at 2-15 p.m. 730 c.cm. of citrated blood was given. The effect was dramatic. As the patient's colour improved he regained consciousness, recognised doctor and sister, and was talking naturally before the transfusion was finished.

At 3-45 p.m. the patient asked for some Benger's food and no vomiting followed. The transfusion was followed at 4-15 p.m. by a rigor and a rise of temperature to 102°F. at 6 p.m., falling to 98°F. at 11 p.m. The following day he had so much improved that it was difficult to imagine he had been so ill on arrival.

On February 10th, 1927, the patient had picked up from his wasted condition. Seventeen days after admission his weight had been 12 st. 7 lb., and by the date of discharge it had reached 14 st. 2 lb. At the same time the blood showed 5,240,000 red cells and 95 per cent. of hæmoglobin. Up to the time of writing he has had no relapse.

The following a somewhat similar case, is also interesting.

Case 3.—European male, aged 67. Residence in India for 43 years. Family history good, no asthma. Previous illnesses: measles, mumps, varicella, enteric fever (at 14 years), malaria; no definite history of dysentery.

In 1920 diarrhœa commenced with flatulent dyspepsia, and was diagnosed as colitis. Improvement occurred on return to England on holiday, but on the voyage to India again in 1925 the diarrhœa recommenced, and for the year previous to admission to the Hospital for Tropical Diseases the stools had been white and bulky.

On entering hospital on July 5th, 1927, he was very wasted and anæmic, and his tongue was glazed and flabby and sore; the abdominal wall was wasted, but the abdomen was not distended; the liver was slightly diminished and he showed a typical picture of severe sprue. Blood count on admission was red cells 2,540,000, hæmoglobin 65 per cent.; weight 7 st. 3 lb.

As he did not progress under the usual treatment, and as four days later it was found that the red cell count had fallen to 2,020,000, it was decided to transfuse with whole blood.

The patient was found to belong to group III, a suitable donor was procured, and on July 12th, 1927, the patient's serum was tested against the donor's blood and no incompatibility was noted. The citrate method was used, with all the usual precautions, the blood being given by the needle and funnel method into the right cephalic vein. Transfusion was started at 2-30 p.m. and at once symptoms of hæmolysis and

anaphylaxis manifested themselves. The needle was at once withdrawn, not more than 5 c.cm. having been given. The symptoms, in order of appearance, were: coughing, nausea, flushing; coldness of the skin, which became clammy, cyanosis of lips, vomiting, pulse accelerated but regular and feeble; severe pain in lumbar region; diarrhoea and shivering. The diarrhoea and shivering persisted at intervals till 5 p.m. At 6 p.m. the temperature had risen to 102°F., but by then his condition had improved. The following morning he was much better, he had had some sleep during the night, and was able to take fluids. No micturition occurred till 5-30, an interval of 26½ hours after the commencement of the transfusion, and then he passed 5 oz. of smoky urine containing albumin, a few red blood cells, hæmoglobin, and both blood and hyaline casts. He continued to make satisfactory progress. Six days later: red cells 2,200,000, hæmoglobin 65 per cent., albumin and granular casts present. Ten days later: red cells 3,040,000 hæmoglobin 70 per cent. Twenty-one days later; red cells 3,840,000, hæmoglobin 75 per cent., albumin, no casts. Forty-one days later: red cells 4,460,000, hæmoglobin 85 per cent., albumin, faint trace. The weight was 7 st. 13 lb., a gain of 10 lb., and he was able to walk a little in the ward. His progress is still satisfactory.

Case 1 is interesting as showing how useful transfusion can be in the most advanced cases. A red count of 600,000 with 22 per cent. hæmoglobin indicates a condition from which few could hope to recover. After the transfusions the patient kept well until three years later, when another transfusion became necessary. Up to the present this patient maintains satisfactory health (one year later). Three years is the longest period that has elapsed since transfusion in any of our sprue cases, but there is reason to expect that some of our later cases may recover completely, and require no further transfusions.

Case 2 is an example of the dramatic effect sometimes attained by transfusion. The rapid recovery from unconsciousness and the subsequent steady improvement greatly impressed all who saw the case, and convinced them that transfusion is essential in all such severe cases.

Case 3 presents many features of interest, the chief being: (1) the occurrence of the hæmolytic and anaphylactic symptoms, although no incompatibility was noticed when the bloods were previously tested; (2) the rapid recovery from the sprue condition though so small an amount of blood had been injected.

Conclusions.

Blood transfusion has now been established as a most important method of treatment in sprue. It would appear that the amount of blood given is not the important factor, though in cases like No. 1, where the patient's blood had fallen to a dangerously low level, a large amount of fresh blood would undoubtedly be a distinct benefit. The important factor seems to be that the blood injected stimulates the blood-forming tissues of the body. How this takes place is a matter for further investigation, but the blood seems to act in somewhat the same manner as do proteins injected in "protein shock" treatment.

In patients who have sustained a slight rigor or pyrexia following transfusion, the beneficent results appear to be as good and perhaps even more rapid in their appearance than in those cases where no rigor or pyrexia has appeared.

Cases of hæmolytic or anaphylaxis are fortunately rare. Case 1 had no symptoms, although the second transfusion, given three years after the first, might have caused them. Case 3 gave no history of previous injection of serum or protein and had no asthmatic history, and yet such severe symptoms occurred that life was only preserved by the prompt recognition of the onset anaphylaxis and hæmolytic and immediate cessation of the transfusion.

As regards the treatment of sprue generally, several points of interest may be mentioned: first, the use of liver extracts in the form of liver soup; and secondly, the use of the so-called pulvis batavia. Recently Dr. George Minot, of Boston, in an address delivered before the American physicians, claimed that liver, and especially a fractional alcoholic extract thereof, is a specific in the treatment of pernicious anæmia. In the discussion that followed Dr. Bailey K. Ashford pointed out its remarkable efficacy in the treatment of the so-called "pernicious anæmias" of sprue. The use of liver in sprue goes back for 30 years or more. Castellani states that it is an old native remedy in Ceylon. It was extensively used by Sir Patrick Manson, and one of us (G. C. L.) has also used it for the last 20 years in an extensive practice of this disease. Though no very startling results can be claimed for it, it does seem to do good, and there is no reason why it should not, as the liver is shrunken in sprue and very probably does not secrete properly. We may, then, by giving liver extracts, supplement this deficiency.

Batavia powder is a specially prepared organic compound of lime, with traces of iron and manganese. It contains no vegetable matter. It is the ancient "Peter Sys's cure," which was used extensively in Singapore in the old days. Originally supposed to come from cuttle-fish bones, it is now prepared from ordinary lime and is a proprietary preparation still. It may act by supplementing the deficiency of lime which is present in the disease, but it also seems to act beneficially in controlling the diarrhoea. It may be given in 1 drachm doses twice or three times a day and continued until the stool becomes solid and well formed. It seems to have a real use in the treatment of the disease.

Solutions of Dyestuffs in Glycerine in Surgical Therapeutics.

By VALDEMAR PLETH, M.D., PH.D.

Americal Jour. Surgery, 1927, Vol. II, p. 239.

FROM the researches of Compton and others it would appear that glycerine has an antiseptic rather than a bactericidal action, and is far less toxic to leucocytes than to bacteria. The author, who has used propyl alcohol for years in the applications of antiseptic dyes to wounds, found that its use was sometimes painful, and hence investigated the possibility of using glycerine instead. Thus the action of malachite green, fuchsin, crystal violet, and brilliant green in solution in 30 per cent. glycerine was investigated. The cases experimented upon were chiefly cases of empyema and of septic arthritis. The following are his conclusions:—

Glycerine is a very efficient antiseptic, yet not toxic to the leucocytes in strength below 41 per cent.

Glycerine indicates a bacterial indifferent zone of cytobacterial activity.

Glycerine-dyestuff suspensions cause no irritation in the most painful wounds.

Suspensions of dyestuffs in 25 per cent. propyl alcohol have proved to be excellent skin disinfectants.

The best bactericidal results can be had by applying the solutions hot.

Not only are the dyestuff solutions more toxic for Gram-positive bacteria when applied hot than when applied cold, but also when applied hot they become bacteriostatic for certain Gram-negative organisms on which, when applied cold, they are quite without effect.

The healing time of infected wounds is materially reduced by this method.

The Baths of Bath.

AN interesting event of last year was the opening at Bath of the Old Royal Baths, an extension to the existing baths. This building was designed by John

Wood in 1777, and to a large extent the lines of the original design have been retained; the new extension providing much needed additional accommodation, delightful in its quiet and restful comfort, a little gem of Georgian setting, its use perpetuating the use of the Hot Spring with its history of nearly a thousand years of healing.

The water in the Hot Spring issues at a temperature of 120°F., and it has been found possible, by sinking a small glass-lined well, to obtain the water by natural flow direct from the spring without recourse to pumping. The water differs from that in the King's Spring, which is served in the Grand Pump Room, chiefly in its smaller content of calcium, sodium sulphate, and iron, and in its larger proportion of sodium chloride.

This new department of the Bathing Establishment has been set apart for intestinal douche treatment (Plombières douches), for which the Bath Waters have proved to be particularly suitable. At first used almost entirely in cases of colitis, Plombières douches have lately been largely prescribed in the treatment of rheumatic diseases, and their growing use has necessitated the provision of more and more accommodation. Special attention has been given at Bath to the administration of intestinal douches, the staff receiving the most thorough and careful training, and by concentrating the treatment in one building, specially designed and fitted with apparatus embodying every improvement science and experience can suggest the highest possible efficiency will be attained.

No case can be taken without medical advice and after every treatment a full report is sent to the physician sending the patient. Cases are sent for diagnostic as well as for treatment purposes, and when desired specimens can be sent for examination and report to the Central Laboratory, which almost adjoins this department of the Baths.

For the other form of treatment to be given at the Old Royal Baths, the historic Hot Bath will be used. John Wood's beautiful little pool bath, with its well proportioned balustrade and graceful carving, has been carefully restored, the only alteration being the addition of a glass roof to enable the bath to be used under any climatic conditions. Even this, when the weather is favourable, may almost all be thrown wide open to the sky.

The treatment, which consists in active and passive re-educative movements, is chiefly used in cases of spastic and flaccid paralysis, and has also been found useful in Parkinsonianism. Experience gained during the war established the efficacy of this method. The object is to allow voluntary exercise to be taken in a medium which will support the limbs and therefore reduce strain and fatigue. The heat (100 degs. to 101 degs. F.), reduces spasm where present and prevents any feeling of chill, while at the same time the patients are obtaining the benefit of immersion in the mineral water. By means of specially designed lifting and travelling apparatus even helpless patients may without the slightest discomfort be raised in the dressing room and carried out over the pool and gently lowered into the water for the movements. Provision is also made for walking exercise in the bath.

Reviews.

LEAGUE OF NATIONS. HEALTH ORGANISATION. PRINCIPLES AND METHODS OF ANTI-MALARIAL MEASURES IN EUROPE. SECOND GENERAL REPORT OF THE MALARIAL COMMISSION. Geneva: 1927.

It will be remembered that after the war malaria in the countries of Central Europe assumed severe epidemic proportions and a Malaria Commission of the

Health Organisation of the League of Nations was appointed to tour these countries and inspect and report on the incidence of malaria and on the measures likely to be possible and effective in combating the disease. In their report on this tour the Commissioners came to the conclusion that for the countries in Europe mainly affected by malaria, the most hopeful measures are those that might be termed "domestic," that malaria as they found it was essentially a house disease and that grandiose schemes of larval destruction on a large scale are not only unlikely to be really successful but that these would be entirely beyond the means of the countries involved. In the present report the Commission reviewed the situation again and state their conclusions and views on measures for dealing with malaria in Europe. This forms the main section of the report, but there are other sections dealing with the arrangements for studying malaria and a discussion on its prevention and control.

The countries in Europe seriously affected are Spain, Italy (and Sicily), parts of Russia, and the group of Central European States bordered by Austria and Hungary on the North, and Greece on the South. The Commission toured these parts, and also Palestine. They give a sober warning against undue optimism in launching anti-malarial campaigns without due consideration and investigation of the problems involved. Most of such campaigns are records of exaggerated expectations followed by disappointment and abandonment. Continuous and renewed study of the disease in all its aspects must still be the prelude to action. The discovery of the mosquito cycle has not put in our hands any single simple method of malarial prevention capable of universal application. Sir Ronald Ross after his recent tour in India will probably now acquiesce in this. The Commission point out that complete eradication of malaria is an ideal seldom obtainable, while measures for the reduction in the incidence and severity of the disease are within the bounds of possibility and that at present the bounds of possibility should not be overstepped.

The common belief since Ross' discovery is that to reduce malaria, it is necessary to use some method involving this discovery. The Commission consider this belief a "tyranny which has been exercised over man's minds during the last thirty years." In England, the Netherlands and Denmark, malaria was abolished or reduced long before the mosquito carriage of malaria was known and without any reduction of anophelines. There is no method of choice in malaria control superior to all others; and every place, almost every village, almost every house is a distinct problem by itself to be studied and solved as such.

Measures of control cannot be begun without preliminary study and continuity of work and inspection, and periodic estimations of the malaria are essential. Having chosen the most suitable method or methods, these should be pushed beyond what the commission call the "minimal effective degree of perversion." By this is meant that a certain amount of action is necessary before any reduction in malaria is perceptible. Readers of Ross' *Prevention of Malaria* are familiar with his treatment of this aspect of the problem by mathematical methods. A slavish copy copying of one country's methods by another should be avoided. "Bonifaction" for instance even in Europe is misunderstood. It is mainly considered to be an anti-larval measure purely and simply. It is nothing of the sort. It is an improvement in the land to make it cultivatable, followed by intensive cultivation and permanent human settling, with an economic improvement in the conditions (housing, feeding, education, etc.), of the actual settlers. "Bonifaction" exploited by financiers without improvement in all these conditions of the agricultural labourers has been and will be a failure in reducing malaria. Nevertheless even where Anopheles prevalence has not been reduced at all, "bonifaction," correctly conceived and carried out in its entirety, has resulted in distinct malarial reduction. Italy has

never placed anti-larval measures in the forefront of her programme. For European conditions, the Commission recommend "direct" measures, viz., killing of the parasites in man by treatment, and killing of the parasites in the mosquito by destroying the adult female anophelines in houses. They advise these as routine measures in preference to all anti-larval methods, which they class as "indirect" measures. These "direct" measures they consider indispensable.

"We are persuaded that the wide distribution of quinine is a public duty, which whenever and wherever necessary, should be organised and paid for by the State."

The Commission are therefore impressed with the necessity of utilising the general practitioner as a "part time malarial officer," but he must be specially educated in malarial work. In Europe, where the local practitioner has a full knowledge of malaria the malarial incidence can be ascertained, but otherwise the Commission found that in very malarious places the local practitioners returned "nil" for spleen and parasitic indices. It is the general practitioner alone who can carry out the first of the "direct" measures above.

This now has a distinct bearing on the Indian problem. We in India do not make use of our practitioners enough in preventive work, and a scheme of malarial control in India should certainly include these practitioners, where they have had the necessary training and experience.

That there is at present no royal road and no short cut to the control of malaria is the burden of the Commission's opinion.

The Commission insists on the necessity for efficient education of the general practitioner in malarial diseases.

The conclusions of the Commissions are perhaps not as rosy as might have been hoped for, but they have done a great service in stating clearly the present position and in refusing to be carried away by unreasonable hopes; what is true of malaria is true of all disease, "the fight against malaria must be waged not as a separate and isolated task, but as part of a social, economic and sanitary campaign directed by an enlightened health service which is able to obtain assistance from other government departments and from unofficial agencies and to secure continuity of action in unity of purpose."

Though the Commission's report refers entirely to Europe, its conclusions and arguments are by no means without interest or application to India. The economic factor in malaria has been insisted on by Christophers and Bentley, but the conditions of land tenure peculiar to India militate against obtaining the full benefits of "bonifaction": the anti-larval school is exemplified in the East chiefly by Sir Malcolm Watson, Strickland and Christophers.

Section II gives a brief but adequate account of the methods of artificial infection of mosquitoes and man worked out by James, of malarial surveys and estimation. Under "prevention and control" they advise the formation of an "Anti-malarial Advisory Committee" in every country, on which would sit representatives of all departments. They insist on adequate treatment and agree that a mixture of alkaloids is cheaper and just as effective, if not more so, than purified quinine. In the Netherlands liquid paraffin is preferred to all other larvacides for large areas, while for rivers and running streams Paris green has proved better.

Anti-larval methods have been found successful only in two areas, viz., in the dry waterless hills of the Kant mountains and in the town of Jerusalem. Koch stated "It is beyond human power to destroy or even reduce considerably a species of insect like the Anopheles in large districts."

The Commission agree with this dictum and recommend anti-larval methods on a large scale only in specially suitable and selected districts where breeding places are small in number and easily controlled.

The eradication of malaria in India is probably a hopeless proposition for many years, but its reduction should be possible; but how can there be obtained that "minimal effective degree of perversion" of anti-malarial work short of which little or no result may be expected?

A. D. S.

THE LISTER INSTITUTE FOR PREVENTIVE MEDICINE. COLLECTED PAPERS. VOL. XX; FOR 1923-24. VOL. XXI; FOR 1924-25. VOL. XXII; 1925-26.

We have received through the courtesy of the Lister Institute copies of these three splendid volumes, which—we presume—are for personal and private distribution to workers interested in the same or similar lines of research work. The custom of binding together into one large annual volume reprints of the contributions made to the literature by the different members of the staff of a large medical research institute is an exceedingly good one; for it enables such institutions to exchange views, ideas, and information in a much more efficient and thorough manner than when exchanges are left to individual members of the staff.

These volumes include many notable additions to medical knowledge. Each is divided into two parts; Part I, bacteriological, epidemiological, pathological and statistical papers; and Part II, biochemical, physiological and zoological papers. In Vol. XX, especially notable papers are Dr. J. A. Arkwright's studies of the bacteriophage; Dr. A. W. Bacot and Dr. C. J. Martin's study of the respective influences of temperature and humidity upon the survival of the rat flea (*Xenopsylla cheopis*) away from its host; a study of tularæmia in man from laboratory infection by Drs. Ledingham and Fraser; and above all Major Greenwood's valuable account of the life and scientific work of A. W. Bacot, whose loss was a severe blow to medical research, and whose splendid pioneer work during and after the war on trench fever and typhus did much to clear up the problems of the ætiology and transmission of these diseases. In Part II, there are included no less than 28 papers, notable amongst which are the nutritional studies by Dr. Harriette Chick and Dr. Margaret Boas; the vitamine studies by Dr. Goldblatt and his colleagues; and Dr. Lumsden's studies of the regulation of respiration.

In Vol. XXI, Dr. Arkwright's short paper on the Rickettsia as ætiological factors in disease is of special interest; also Dr. Mary Cowan's studies on the variation in virulence of different strains of streptococci. Dr. Ledingham contributes a detailed study, illustrated by colour plates, of the reaction of the skin to vaccinia virus, and a short note reprinted from the *Lancet* on the relationship of alastrim to variola, as studied from the experimental point of view. Part II includes 26 papers, almost all of them dealing with nutritional problems, vitamins, and metabolic studies.

In Vol. XXII, the most important reprints perhaps are those of the Harben Lectures, 1925, delivered by Professor J. C. G. Ledingham. The first deals with some problems of natural immunity and prophylaxis; the second with the carrier problem in relation to enteric fever and diphtheria; the third with studies on variola, vaccinia and avian molluscum. The relationship of the sexual glands to metabolism is the subject of a series of papers by V. Korenchevsky and Marjorie Carr. Dr. Lumsden's studies in the experimental treatment of implanted malignant tumours of the rat by an anti-serum suggest that such an anti-serum may come to be of special value in man, when administered in conjunction with surgical removal of malignant growths. In Part II there is again a large series of papers dealing with nutritional problems, vitamins, metabolism, and the action of ultra-violet light on food-stuffs. Notable contributors to the volume are Dr. Harriette Chick, Dr. Margaret Boas,—who deals with the anti-rachitic value of winter spinach; and Dr. Margaret Roscoe, who in a joint paper with Dr. Chick,

deals with the influence of diet and sunlight on the amount of vitamins A and D in the milk of a cow; it was found that the richest content of both vitamins occurred when the cow was out at pasture in the summer. H. D. Kay deals with the variation in the end products of bacterial fermentation, resulting from increased combined oxygen in the substrate; and Ida S. Maclean and Dorothy Hoffert on the carbohydrate and fat metabolism of yeast.

The annual collected papers of the Lister Institute should be in the library of every large medical research institute in India. The Lister Institute has always been foremost in its studies of metabolism, nutritional problems, and vitamin studies; and the three volumes for 1923-26 show what an enormous amount of valuable investigation is being carried out at the Institute in many fields of work.

LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE. COLLECTED ADDRESSES AND LABORATORY STUDIES. VOL. II; FOR THE YEAR 1925-26.—Compiled by Prof. R. T. Lelper.

We very much regret the delay in reviewing this sumptuous and most valuable volume. Like the Lister Institute for Preventive Medicine, the London School of Hygiene and Tropical Medicine follows the admirable custom of annually binding together in one volume reprints of the publications during the year by members of its staff, for distribution to other medical research institutions and schools of tropical medicine all over the world. We presume that this volume is for private circulation only, and not for sale; but there must be many old students of the London School in India who will be interested to know of it. The volume includes three addresses by Dr. Andrew Balfour, and reprints of 32 papers by the members of the staff.

Dr. Andrew Balfour's addresses are always fascinating reading, for they are based on a knowledge, a wide experience, a charming literary style, and an earnestness of purpose which it would be hard to match. "Why Hygiene Pays"—an address to the delegates attending the West Indian Conference held in London in May 1925, has already been reviewed in our columns. It is a very striking and forceful essay, and one which will provide much powder and shot for the public health propagandist. "Some British and American Pioneers in tropical medicine and hygiene"—Dr. Balfour's presidential address to the Royal Society of Tropical Medicine and Hygiene—is an outstanding contribution to the literature of both medical history and tropical medicine. India may study this address, with its wonderful gallery of portraits, with much advantage and with no little pride, for workers in India are prominent amongst the pioneers mentioned in it. Further, the address is in Dr. Balfour's most delightful and pleasant literary style. The third address is a brief one on "Some landmarks in tropical medicine," given to the Cambridge University Medical Society.

Turning to the laboratory studies, we have here such a wealth of valuable material that it is impossible within a short space to give any adequate account of it. Several of these papers, however, have been previously reviewed in our columns. The short paper by Dr. P. A. Buxton and Mr. G. H. E. Hopkins on "Race suicide in *Stegomyia*" is an account of a search for a fluid which should prove so attractive to the female *Stegomyia* that she will lay her eggs on it in preference to any other site; once the eggs are laid they can then be destroyed at regular intervals. It is precisely by such biological and bionomic studies that the cause of anti-mosquito campaigns is likely to be most advanced. We want a thorough study of the habits of mosquitoes; of their natural enemies—whether protozoal, helminthic, or in the insect world; of the factors which affect their breeding grounds, both with regard to selection of sites and development of

the larvæ. This field is a pioneer one, only the fringes of which have been explored as yet; but it is one of great promise, and Dr. Buxton, Dr. Williamson of Singapore, and Mr. Senior-White of the Central Malaria Bureau at Delhi are amongst others who have made important contributions to our knowledge in the matter.

Dr. E. Hindle and Dr. J. T. Duncan conclude that when bacteria are ingested by *Argas persicus*, they remain confined to its intestinal tract and are gradually eliminated through the faeces; this tick is therefore not a likely transmitter of bacterial infections. Drs. J. C. Thomson and A. Robertson contribute a series of papers of protozoological interest and importance; they have cultivated both the intestinal entamœbæ and flagellate protozoa of man by the technique of Boeck and Drbohlav; have studied the natural herpetomonads and crithidias of anopheline and culicine mosquitoes; have demonstrated that the coccidia of the genus *Eimeria* in human faeces are natural parasites of fish, have nothing to do with man, and are only ingested by him, when they may be found in the faeces of a patient on a fish diet; whilst Drs. J. G. Thomson and C. L. T. Lucas describe the common entamœba of the cockroach—a paper illustrated with useful and original plates, and discuss the status of the genus *Endamœba*. Major H. C. Brown, i.m.s. (ret'd.), and Drs. H. C. Duncan and T. A. Henry discuss the differentiation of food-poisoning bacteria, giving a useful table of differential cultural reactions. Miss M. J. Triffitt describes entamœbæ found in African antelopes and water buck—a paper illustrated by a very good plate; also protozoal parasites allied to the genera *Lymphocystis* and *Eimeria* found in the intestinal wall of Bennett's wallaby—a paper with a useful bibliography.

A paper of special interest is one by Dr. P. A. Buxton on the depopulation of the New Hebrides and other parts of Melanesia. He considers that, whilst tribal wars, septic midwifery, and the practice of abortion and other customs may have seriously contributed to depopulation in the past, the factors which are mostly at work at present are different. It is association with European civilisation that is largely responsible; whilst the Government is a Condominium, which moves at snail's pace, so that administration is uncertain and slow, whilst free medical treatment has not yet been provided. Alcohol is a big factor, also the destruction of communal life and interests by missionary proselytisation. Of the endemic diseases malaria and yaws are important because they render the race unhealthy and liable to succumb to imported epidemics, of which dysentery and pulmonary tuberculosis are the two most important. The race continues to decline, whilst there is a great excess of male births over female (118 to 100). The extinction of the race would appear to be only a matter of time, unless vigorous measures are taken.

Dr. H. B. Newham contributes a report on the chemical analysis of the stools in sprue, and Dr. J. G. Thomson a good—but all too brief—paper on pseudo-parasites in the faeces of man. (This subject very badly wants working up in the interests of protozoologists and helminthologists alike). Dr. J. T. Duncan has investigated the bactericidal principle present in the alimentary tract of flies, mosquitoes, and ticks; the action of this principle is more like that of an antiseptic than of the bacteriophage, and it is possibly of the nature of an intestinal secretion. The presence of such an agent might play an important part in rendering the gut of such insects sterile and therefore suitable for the transmission of certain blood-inhabiting protozoa.

There is a wealth of helminthological papers in the volume. Professor Leiper deals with Dr. Sambon's claims that the *Gongylonema* worm may have something to do with the causation of gastric carcinoma in man, and concludes that all the evidence available is against such a hypothesis. Dr. H. B. Newham deals with *Clonorchis* infection of the pancreas; Dr. T.

Goodey with a nematode causing galls on the roots of barley; with an *Ascaris* from the sheep; a nematode found in diseased potato tubers; and the genus *Strongyloides*. Dr. R. J. Ortlepp describes nematode parasites from the gizzard of the peafowl, and reviews the genus *Streptopharagus*. Dr. T. W. M. Cameron deals with the genus *Echinococcus*, describes a new species of *Trichostrongyloid* worm from Bennett's wallaby, and discusses the lungworms.

The whole volume is full of interesting matter, and well emphasises how vigorous and active the London School is in its new and extended functions. It is one which will appeal especially to the parasitologist and the laboratory worker, whilst the public health officer in the tropics will find much of interest in it, especially in Dr. Balfour's addresses. It is well bound, and of a convenient size to handle.

MEDICAL RESEARCH COUNCIL. SPECIAL REPORT SERIES, NO. III. THE SPREAD OF DROPLET INFECTION IN SEMI-ISOLATED COMMUNITIES.

—By Surgeon-Commander Sheldon F. Dudley, R.N. Pp. 61. London, H. M. Stationery Office: Indian agents, Thacker, Spink and Co., Calcutta, and others. Price, 1s. 6d.

THAT droplet infection is a serious menace in India is shown by the terrible influenza pandemic in this country in 1917-18; by the terrible prevalence of tuberculosis due to infection with the bacillus of human type; and by the special prevalence at certain times of the year of diphtheria, infectious coryza, and other respiratory complaints. A study of the spread of such epidemics in the general population at large, however, involves the interaction of so many different factors that it is well-nigh impossible. In a limited or semi-limited community, on the other hand, the factors at work are less obscure, and the Royal Naval School at Greenwich offered such an opportunity to Surgeon-Commander Dudley. In the preface to this booklet, the Medical Research Council explain the conditions under which the enquiry came to be carried out as follows:—

The laws which govern the onset and decline of epidemics of infectious disease are still only known in small part. For the population at large, living in unrestricted inter-communication, the conditions are so complex that accurate observation is difficult and often becomes almost impossible. Much more hopeful are attempts to solve the problems, one by one, by the experimental method applied in suitable animal communities. The Council have been glad on that account to give their support to the novel and ingenious studies in experimental epidemiology initiated by Professor W. C. Topley, and recently the subject of a fruitful collaboration between him and Dr. Major Greenwood.

It has been sometimes overlooked, however, that there is another line of attack hardly less promising than the direct experimental method, where the conditions are favourable. There are some communities sufficiently isolated and under control to have much the same value for purposes of study as a group of animals under experimental conditions, and they may give at the same time some added advantages. It so happens that the Royal Navy includes several semi-isolated communities of this sort, and it is to the credit of Surgeon-Commander Dudley, R.N., that he has grasped the opportunities which they offer for the study of epidemiological problems, and for the improvement of our mastery over the spread of disease. One of the most suitable communities for the purpose is the Royal Naval School at Greenwich, and three years ago the Council published in this Special Report Series (No. 75), by permission of the Admiralty, a report by Surgeon-Commander Dudley upon his studies of the natural history of diphtheria and scarlet fever at this school which they believed to have a high value.

No less interest attaches to this second report in which the writer has carried his investigations further. He extends them to some other diseases which, like

diphtheria, are spread chiefly by droplet infection from the respiratory tract, and he compares the observations made at the Royal Naval School with similar facts gained from other semi-isolated naval communities and from the Foundling Hospital.

The conclusions emerging from these recent studies have much importance. Thus, as regards the fluctuations in herd-immunity and its relation to the introduction of new elements of population, the conclusions reached at Greenwich are strikingly similar to those reached by Professor Topley and Dr. Greenwood in their studies of communities of mice maintained under defined conditions; this confirmation of the animal results by actual observation of a human population inspires confidence in both sets of studies. Surgeon-Commander Dudley's own previously enunciated hypothesis as to "velocity of infection" is amplified and illustrated anew in the present report, as is the great importance of relative isolation in sleeping quarters, first brought out by Glover in his studies of meningococcus carriers, published in the Report in this series (No. 50) upon Cerebrospinal Fever among the Military Forces.

It can only be by the repeated collection and study of individual facts from many sides that the laws of epidemiology will ultimately be established. Much more work of the nature and quality of that set forth by Surgeon-Commander Dudley in this Report is needed, and in time will doubtless be forthcoming. Our practical need for better knowledge of this subject for the purposes of prevention is obvious indeed, and it will always be most obvious to those responsible for the proper care and management of definite communities like those, for instance, within the Fighting Services.

In summarising his conclusions, Surgeon-Commander Dudley enumerates one by one the different factors concerned in the spread of air-borne epidemic disease in a community, and draws attention to the necessity of providing adequate sleeping accommodation. He concludes, however, that the problems raised should receive much further study. He writes as follows:—

Summary.

The important conclusions reached by this study of the ecology of man and some of his dependent organisms are:

- (1) Host resistance to parasitic infection may be specific or non-specific.
- (2) Specific resistance depends on the nature and amount of previous contact with the proteins of the specific parasite.
- (3) Non-specific resistance may be an inherent property of the host's germ-plasm, or due to contact with other non-specific proteins. (Non-specific resistance is so important that it must just be mentioned, though it has not been discussed in this paper.)
- (4) Resistance to parasitic infection may be of any magnitude, duration, or variability.
- (5) The resistance of the population as a whole to the spread of disease outbreaks may be termed "herd immunity."
- (6) The ratio of the number of individuals with a resistance above a certain magnitude (immunes) to the number below this magnitude (susceptibles) may be termed the "herd immunity index."
- (7) The ease of spread of epidemics in space and time is a function of this index, combined with the density, and type of motion, of the herd.
- (8) Moreover, there is evidence that the symptom-producing power (pathogenicity) of parasites is in some way correlated with the "herd immunity index."
- (9) The periodicity of epidemics can be more easily understood if parasitic "virulence" and antigenic (or immunizing) power vary inversely as the degree of herd immunity; and there are now a number of observations consistent with such an hypothesis.

(10) A certain minimum mass of infective agent is required before a dependent organism can establish itself in its host.

(11) Less than this amount will be destroyed by the host and cause some alteration in the degree of resistance.

(12) Time spent in an infective environment therefore becomes of importance, not only as regards the number of opportunities of receiving an infective dose as a whole, but because sub-infective doses can be summed to an infective one, or destroyed, thereby altering the resistance of the host.

(13) The quantitative factors of time, mass of infective agent, and degree of host resistance make it essential to introduce three "velocities" into the study of infection.

(a) The velocity at which the infective material is received by the host.

(b) The velocity at which it is destroyed by the host.

(c) The velocity at which the host resistance alters in a positive or negative direction.

The resultant of these three is the "velocity of infection," on whose magnitude depends the final result of the reaction between the host and the dependent organism. This result may be an illness mild or severe, the establishment of tolerance (i.e., commensalism or the carrier state), or the destruction of the parasite; and in all cases there will be change in the host's defensive mechanisms, for better or worse.

(14) The distribution of infectious disease in time is a function of the rate at which the host population changes.

(15) The chief practical lesson this paper teaches is that the individuals of a community should be isolated from each other to the greatest extent possible in their sleeping quarters. Especially is this the case in those communities to which many susceptibles are frequently added.

Conclusion.

It stands to reason that if the principles enunciated in this paper are sound when applied to the spread of disease in semi-isolated communities, they must also be applicable to the world at large; but they are not so evident in the world at large owing to the infinite number of complex and overlapping environments. The rate of change in the world as a whole is a function of the birth and death rates and average expectation of life. The new-born babies are the recruits to the population, and hence the overwhelming morbidity of infectious disease among children as compared with adults. The new-born babe seems to possess a remarkable immunity to certain infections, which is often casually explained as being due to its protected environment. As a matter of fact the opportunities which a new-born babe has of receiving doses of any bacteria that may be in the environment are considerable. A baby is fondled and caressed by all its immediate fellow mammals, and it really is remarkable that infantile mortality should be as low as it is. But during the struggle for existence and the elimination of the unfit, a mechanism has arisen whereby new-born mammals are adapted to combat the different types of bacterial environments they may be born into. In the way previously described a mother acquires a certain degree of resistance to those bacteria she has been in contact with, and this resistance is to some degree passed over via the placenta to her foetus. In the case of diphtheria a woman who has a Schick-negative reaction, that is who has diphtheria antitoxin circulating in her blood, always bears children with a negative reaction. This immunity is subsequently lost, hence it is semi-passive in character.

There are many observations which show that this congenital and often transient immunity is not confined to diphtheria and scarlet fever. A very good example is that of undulant fever. Undulant fever is rarely reported in Maltese infants. Yet 50 per 10,000 is the

notified annual attack rate among the Maltese population, and the real incidence is probably much greater. At the present time 10 per cent. of the goats are reservoirs of *Brucella melitensis*, and agglutination tests and other evidence suggest that many human beings may also be carriers. Thus, though nearly every Maltese infant feeds to a great extent on cultures of *B. melitensis* in goat's or human milk, few show any symptoms of undulant fever. It is just possible some babies may be overwhelmed by massive infection without any symptoms of undulant fever, because the infantile mortality in Malta is so great (280 in 1923), but the writer has not heard of any work attempting to connect this colossal loss of life, with undulant fever. The same apparent immunity of British infants to tubercle bacilli is also remarkable, as at least 10 per cent. of samples of market cow's milk contain *B. tuberculosis*. Therefore the new-born infant acquires a congenital semi-passive immunity which enables it, when necessary, to acquire considerable active immunity before it is overwhelmed by the bacterial environment. In brief, the world's recruits join with a ready-made herd immunity adapted to the place they arrive in.

According to the conclusions reached from this study of the spread of infection in semi-isolated communities, the kind of motion among the human species in the world as a whole has a great bearing on the spread and character of infectious disease in general. Of late years the extent and rate of intermigration has been increasing. It might be thought that this increase in movement would be accompanied by increased morbidity of infectious disease. Possibly in the aggregate this is the case. Certainly, if the motion of the human species is suddenly greatly increased and amplified, the change is correlated with increased symptomatic infection. The epidemics during and after the Great War demonstrated this fact. But, on the other hand, if the rate of the local changes in population or the type of human motion is of a suitable quality, a compensating effect may take place. Bacterial antigens get distributed by the intermigration and produce a rise in the world's herd immunity. Sufficient intermigration should prevent the repetition of those catastrophes which sometimes occur in "unsalted" populations, such as the measles epidemic in the Fiji Islands. In some conditions, such as scarlet fever, where fatality is definitely on the wane while morbidity is increasing, both the malignant and beneficial effect of intermigration are perchance seen at work together. However, the difficulty of interpreting correctly the meaning of infectious phenomena is great enough in small communities, where some at least of the conditions are more or less controlled; but this difficulty becomes infinitely greater when applied to the world at large, and the writer realizes that the real significance of the facts described in this paper may often have been missed. The study of infectious disease, with its constantly changing distribution in time and space, is a problem in the physiology, ecology, and bionomics of parasites. The relations between man, his dependent organisms, and the external environment are in a constant state of flux. The numerous factors involved all react on each other, and the relative value of each factor varies with every complex of host and parasite. As Haldane has recently said of biological problems, "We are everywhere baffled by indefiniteness and complexity due to the fact that each phenomenon, whether of apparent structure or apparent activity, is relative to other phenomena."

MEDICAL RESEARCH COUNCIL. SPECIAL REPORT SERIES, NO. 115. THE PREVENTION OF DIPHTHERIA.—By Dr. J. Graham Forbes, M.D., F.R.C.P., D.P.H., Principal Assistant Medical Officer, London County Council. Pp. 84. London, H. M. Stationery Office, 1927. Price, 2s. net.

THE last century saw, in 1894, the introduction of anti-diphtheritic serum, an innovation which has reduced the case mortality in diphtheria from 30 per cent.

to 7 per cent. The present century, during recent years, has seen the introduction of the Schick test for immunity against diphtheria, and this test is now being very widely used all over the world in testing school children and others. The brochure here under review consists of an analysis of the results obtained in many different countries, with suggestions for the practical control of the disease. It was primarily written for the London County Council. In giving a prefatory sketch of the objects and results of Dr. Graham Forbes' enquiry, the Medical Research Council write as follows:—

The present Report offers a comprehensive survey of the methods of diphtheria prevention which have been practised upon a large scale for the past ten years in America and to a much less though growing extent in Great Britain. It throws clear light on the stages in the progressive application to practical life of measures founded upon a generation of effort in the laboratory. It is a valuable complement to the chapter upon the prevention of diphtheria in the monograph upon the disease which was published by the Council in 1923.

What the use of antitoxin, introduced in 1894, has done to improve the treatment of the disease, the method of detecting susceptibles by the Schick test, combined with their protection by toxoid-antitoxin immunization, is now doing for its prevention. All we know of the natural history of the disease and its attack on mankind shows the special urgency of the need for prevention in the present generation. The antitoxin treatment of the disease brought down the case mortality quickly from 30 per cent. to below 10 per cent., but since 1904 the decline, though continued, has only been from about 9 to about 7 per cent. During the whole time of the use of this life-saving method, the attack rate and the virulence of the disease have been increasing. In London, for instance, between 1904 and 1924 the attack rate per 1,000 persons living rose from 11.2 to 19.1 and the deaths from 0.99 to 1.33. The great saving of life given by the antitoxin treatment has held in check the total deaths, though we can see clearly what far greater sacrifice of life there must have been without it. Happily, the advance of knowledge by research has progressively given, during these very years of the growing strength of the disease, effective means for its preventive control. The results already gained by their aid, first by imperfect methods and later by the improved methods now available, are collected and set out in this Report.

In this country we shall owe much, as will be seen, to the pioneer work in the practical application of these preventive methods made during recent years in America. It will be noticed that in Great Britain, Scotland has been foremost in putting this new knowledge to use. It appears that, at the present time, of children under 15 in the general population and not within institutions, five times as many have been immunized in Scotland as in England and Wales together, or over forty times as many in proportion to the population. Including those in hospitals and schools, the total number of persons immunized in Scotland is more than double that of those immunized in England and Wales, or about eighteen times as many in proportion to the population.

In compiling this Report Dr. Graham Forbes has naturally focussed his attention upon the need for protecting the child population of London at the pre-school and early school ages. The results of his inquiry show unmistakably that diphtheria in London has a higher rate of incidence and of mortality than in almost any other European capital, and a higher rate of both than in any other large city in Great Britain. The large body of evidence already available leaves no doubt that the disease and its often fatal consequences may now fairly be called avoidable. The experience already gained during recent years and in so many places imposes upon every public health authority the responsibility of giving serious consideration to the

provision of means now available for protecting life, and especially young life, from the menace of a disease whose prevalence and malignancy have been increasing of late years and seem more likely to increase still further under present conditions than to diminish. At the same time it should not be overlooked that an important part of this provision is the necessity for making the facts clearly known to all parents, and for instructing them as to the means open to them for the safeguarding of their children.

The author reviews in turn the value, errors, cost, and use of the Schick test—a chapter which will be of practical interest to every public health worker in this country. He then takes up in turn the results of the application of this test as observed in London, Great Britain at large, the United States—where, of course, the test, and active immunisation against diphtheria have been very largely practised; and in other countries. In this connection we are glad to note that he includes the paper published by Fox and MacDonald in this journal (1923), dealing with the application of the test during a diphtheria epidemic in the schools in Shillong. We believe that so far this instance has been the only one of the application of the test in India; its results were to fully confirm the value of the method as applied in India. In his conclusion, the author writes as follows:—

It may be stated that the evidence which has now steadily accumulated in America and is forthcoming, on a more limited scale, from the work done in Great Britain, together with the world-wide use of these measures, appears sufficiently convincing to justify the experienced opinions of all who have devoted much study to the problem, and hold that the Schick test and immunization constitute one of the most notable advances in the sphere of preventive medicine. Furthermore, there is now very little doubt that their systematic adoption would result in a great yearly saving of child life, notably in London, where, though diphtheria has been more generally prevalent and presents a more pressing and difficult problem than in the provinces, no co-ordinated effort has been made to introduce immunization. Reduction in the incidence of the disease would also lighten very materially the burden on the ratepayers of the present heavy expenditure incurred in the existing system of notification, removal, disinfection, isolation, and hospital treatment and in the general preventive measures against the spread of infection in the homes, schools, and elsewhere.

The problem is one calling for the closest co-operation of all authorities concerned, whether Public Health, Administrative, or Educational—and particularly in London, where, for diphtheria, the attack-rate surpasses, and the mortality rate nearly so, that of any other city in Great Britain, and almost every other capital in Europe, if not the world.

Dr. Graham Forbes' report is one which should be in the hands of every medical officer of schools and public health administrator in India.

A TEXTBOOK OF MEDICINE BY AMERICAN AUTHORS.—Edited by Russell L. Cecil, A.B., M.D. London and Philadelphia: W. B. Saunders Co., Ltd., 1927. Pp. xxii plus 1500. Price, 40s. net.

In his preface to this bulky volume the editor points out that medicine has reached such a degree of specialisation that it is impossible for one man to master the entire field. The present work represents the efforts of no fewer than one hundred and thirty contributors, each a specialist in his own particular branch. This has resulted in the production of a textbook of medicine which is certainly one of the most complete we have yet seen. Practically all the latest advances in medicine, so far at least as it concerns temperate climates, are included. The section dealing with tropical diseases is not quite so exhaustive: we did not observe references to the value of plasmochin in

malaria, of organic antimony compounds such as ureastibamine in kala-azar, and of calcium and parathyroid in sprue.

It is impossible to read line by line a book of the dimensions of the volume under review, but in a general survey of the work we detected a gratifying absence of errors: we do not think however that *B. influenza* should be described as a Gram-positive organism (p. 9).

We are confident that this book will find a place among the standard works of reference on the practice of medicine. It remains to congratulate the publishers on the tasteful get-up of the volume: considering the wealth of information supplied the price—forty shillings (roughly Rs. 26)—cannot be considered excessive.

**LEAGUE OF NATIONS, HEALTH ORGANISATION.
STATISTICAL HANDBOOKS SERIES, NO. 8. THE
OFFICIAL VITAL STATISTICS OF THE FRENCH
REPUBLIC. Geneva: 1927.**

THE Health Section of the League of Nations is doing a notable service in preparing this series of handbooks describing the official vital statistics of various countries; the methods of collection, etc., and especially the various publications, where they are set forth and can be obtained.

The vital statistics of France during recent years have been the subject of considerable comment all over the world. To some the falling birth rate is a herald of coming national disaster, to others it seems part of that natural biological adjustment of vital happenings heading towards a stationary population; a desideratum which this class of observer thinks is the goal towards which all civilised nations are tending. The area of a country, its natural resources, its agricultural fertility, and its standard of living are all factors determining what this stationary population will eventually be. In France it appears to be about 39 millions. It is therefore desirable that those interested in these very important aspects of public health should be aware of the methods by which the vital statistics of France are collected, their reliability and how and where this information may be obtained. The present volume, compiled by Prof. Major Greenwood and Major P. Granville Edge, gives this information clearly, simply and in a very interesting and readable manner.

A short description of the system of central government and of the system of local government is given first. The mayor is an important person in the commune and is nominally responsible for the collection of all information. Paris and Lyons have each a special system. Health legislation in the modern sense came with the Third Republic. The law of 1884 provided for departmental and municipal health services. The decree of 1920 established a Ministry of Health, which in 1924 became merged in the Ministry of Labour. The Director of Public Health (who is under the Minister of Labour) is an officer with wide executive powers, and is the central authority for the promulgation of Health measures and for ensuring that all regulations are enforced. To assist him he has a Superior Health Council, a consultative and advisory body. Ports and frontiers have special administrative staffs. In departments and communes the prefect and mayor are responsible for the provision, maintenance, and control of health services. Each department has a disinfection service and certain of them have laboratories for public health work. If the mortality of any commune during three consecutive years exceeds the mean mortality of the whole republic, an enquiry is instituted to determine cause and improvement. Towns over 20,000 must establish a Bureau d'Hygiene. The system is therefore comprehensive and logically conceived. Economic difficulties, however, stand in the way of a full realisation of advantages.

An interesting historical account is given of the collection of statistics. Like the Domesday Book, they

were first used in land tenure administration. Various data were thus collected but not utilised as a whole. To French savants we owe much of the development of the science of probability, and Deparcieux in 1746 contributed the first French life table. Euffon in 1767 published tables of mortality based on death registers. Terray in 1772 instructed all the clergy of Catholic persuasion to keep records of births, deaths and marriages.

In 1799 a general enumeration was ordered, but was not carried out till 1801. All such information is fully collected by various departments and sent to the Direction de la Statistique Generale. Paris itself publishes an *Annuaire Statistique de la Ville de Paris* prepared by the Municipal Statistical Bureau, and in 1922 this contained comparative tables of international mortality. It was not till 1821 that a satisfactory census was taken; from that date 5 yearly census have been done. In 1876 the individual bulletin came into use all over. These are filled in for each individual.

The *Annuaire Statistique de la France*, *Album graphique de la statistique de la France*, and the *Statistique Sanitaire de la France* are the principal publications giving information on the Census.

Registration of births and deaths has been compulsory since 1803, though previous to this a "parish" system kept by parish priests was in vogue. The mayor is now responsible for their collection. These registers are verified and since 1923 registration officials every 3 months send extracts to the Direction de la Statistique Generale de la France. Live births must be registered within 3 days. Presentation of the actual child used to be compulsory but has now been abolished.

Still-births must be registered, and a special form filled in stating the duration of gestation and whether the child breathed or not. Special statistical information is available *re* still-births in the three publications mentioned above.

Deaths since 1803 must be registered, but no time limit is specified. The Mayor is the registrar. There is no legal enactment demanding the cause of death. Under the French Penal Code a medical practitioner must not under pain of severe penalties divulge any information given him during his professional duties. The fact of death must be verified by an official who at the same time usually endeavours to determine and enter the cause of death. The abridged International list of Causes of Death is used. In the "*Annuaire*" for 1921 appears a life table based on the 1911 census. Statistical information relating to diseases is therefore faulty.

Infectious diseases are notifiable, some compulsorily so, others voluntarily. Notification is made to the Mayor. Disinfection services are available, but no mention is made of infectious hospitals. Vaccination against small-pox is compulsory during the first year of life and re-vaccination during the 11th and 21st year of life. After the war tuberculosis was a serious menace and in 1916 the law created Health and Welfare Dispensaries of which now 510 are functioning.

Veneral diseases are also the subject of a special service. There is an interesting note by M. Michel Huber on the census and on "movement of population." He explains that the census is taken for two reasons.

(1) To obtain the legal population of each commune, etc., for the application of fiscal and electoral laws, etc.

(2) To obtain the population present for demographic, economic and social studies.

Two departments therefore collaborate in census taking, the Ministry of the Interior and the Ministry of Labour. Migrational movements, both internal and external, are enumerated as far as this can be done, and are published weekly and every three months.

The handbook is an interesting compilation for which thanks are due to the League of Nations officials.

A. D. S.

DYSPEPSIA AND ITS SELF-TREATMENT.—By J. N. Ganguli, B.A., M.B. Second Edition. Benares: Bharat Dharma Press, 1926. Pp. 270. Price, Rs. 2-12-0.

THIS is the second edition of a little book, the first edition of which was reviewed in our issue for October 1924. It is written by an Indian practitioner of nearly fifty years' standing, and—as it deals especially with Indian conditions, Indian dietaries, and Indian habits, it is a book of special value to the medical practitioner in India; whilst, at the same time, the European medical practitioner in this country who has to deal with Indian patients will find in its pages much information and many suggestions of value. Further, the author's literary style is delightful; page after page is adorned with admirable quotations, and he lays under tribute Susruta, Shakespeare, St. Luke, and the Bhagavad Gita. "Our remedies oft in ourselves do lie," he quotes on his title page, and this theme is well elaborated in his book.

Briefly, the author's contention is that dyspepsia—which is an almost universal condition in India—can be cured by the patient himself (except in severe and exceptional cases, where a doctor must be called in)—if he will but adopt a systematic and orderly routine of life, diet, and exercise. And the book should be particularly welcome to Indian practitioners, since it deals especially with Indian articles and customs of diet. There is much of Ayurveda in this volume (and, from the dietetic point of view, this is to be welcomed and not deplored), and also much of "Western" medicine.

The most important chapters in the book deal with acute and chronic dyspepsias; with the daily life of the chronic dyspeptic—a chapter which is full of excellent and sound common sense; with fasting; mental and nervous treatment; the use of fruits; and exercise. "Why rice eaters become dyspeptic" is a sub-heading to which we should like to call the attention of all Bengal; it is the quality of the rice which is all-important; also, to some extent, the quantity. A Sanskrit proverb advises "Fill half the stomach with food, one fourth with drinks, and leave one fourth for the humours to move in"—not at all bad advice. Lewis Cornaro was a chronic dyspeptic at the age of 40; but thereafter resolved to cut down his allowance of food and drink to 12 ozs. and 14 ozs., respectively. He lived to the age of over 100 years, and counselled that "none should be afraid of shortening their lives by eating too little." The dyspeptic should, above all, avoid three things; "suppers kill more than doctors cure"; avoid feasts; and avoid incompatible foods—and in this last section the author has wise and experienced advice to give, based on a very long experience.

Fasting is one of the author's chief remedies for dyspepsia, and he discusses fully the value of the religious fasts imposed by different religions; no food after sunset should be the golden rule; whilst an occasional 24 to 30 hours' fast is good alike for body and soul. Auto-suggestion, he also claims, has its place in the treatment of dyspepsia, whilst hypnotic suggestion is not to be ignored. Fruit is a most suitable article of diet for the dyspeptic, but it must be carefully selected according to the time of the year, and here useful instructions with regard to Indian fruit dietaries are given.

"Pan" chewing, we note, the author does *not* condemn; he considers that the habit—in moderation, of course,—is of value in stimulating salivary secretion, as a carminative and antacid, and to allay any tendency to diarrhoea and irritative dyspepsia. Probably he is right in this attitude, for the habit has become firmly ingrained in India; the soda-peppermint lozenges of the West are but a substitute for it.

Of exercise and exercises the author has much to say, walking being rightly singled out as of special value for the dyspeptic. Amongst drugs he holds *kurchi* and bael fruit rightly in high value. The concluding

chapter details a "dyspeptic's directory" from A to Z.

Dr. Ganguli's little book is one of both charm and value. Its literary style is delightful: it is the mature fruit of nearly 50 years of experience; it draws inspiration alike from the West and the East; it is full of admirable quotations. Also it is a book alike for the physician and the patient. Finally, it is especially with regard to its special application to Indian conditions that it will be welcomed by the medical profession in this country.

A POCKET GUIDE TO MEDICAL LIFE ASSURANCE.—By J. J. Cursetji, M.D., L.R.C.P., L.R.C.S., L.M. & S. Second Edition. Bombay: "Times of India" Press, 1927. Published by the Oriental Life Assurance Company. Pp. 85, with appendix.

THIS is the second edition of a little book, the first edition of which we had the pleasure of reviewing in our issue for November 1924. As no price is stated, we presume that, like the first edition, the book is intended only for a limited and semi-private circulation to those especially interested in life insurance work in India.

The author has done his work admirably. We could wish, indeed, that he would expand this small book into a larger one for general publication and sale. From first to last the book deals especially with Indian conditions, and the peculiar problems which face the medical examiner of lives in India. Thus, in the examination of Indian women for life insurance, great stress is rightly laid upon the excessive prevalence of puerperal sepsis and its sequelæ in such patients. In Indian males malaria, dysentery, and above all pulmonary tuberculosis are diseases which have to be especially enquired into. Indian proposers are often very ignorant of the life history of their parents, and special care should be taken with regard to this point.

The successive chapters of the book deal with general suggestions as to the carrying out of an examination; medical examination of the applicant; his family and personal history; his present condition, and environment—the latter a factor which may have a profound influence on the expectation of life in Indians. Full details for urine analysis and for auscultatory methods of examination of the pulse pressure are given. A very special feature of this edition is the inclusion at the end of an appendix giving an analysis of average heights, weights, chest and abdominal measurements of Indian assured lives, based on 51,186 Indian lives accepted by the Oriental Government Security Life Assurance Co., Ltd., Bombay. This deals *seriatim* with different Indian races such as Bengali Hindus, Bombay Hindus, C. P. and U. P. Hindus, Madras Hindus, Punjabi Hindus, Indian Christians, Mahomedans, and Parsis. Other useful statistical information is included, chiefly from American sources.

The author is a pioneer in his line, and a study of his book shows—as might have been anticipated—that conditions with reference to life insurance in India are widely different from those in temperate climates. The normal expectations of life at different ages, the commoner diseases, and the environments concerned are completely different in Indian and European conditions. The book is admittedly a "pocket guide," but it will be exceedingly useful to all medical examiners of Indian candidates for life insurance. We trust that it is but a prelude to a larger and more comprehensive work.

It only remains to add that the paper, printing, and illustrations are excellent—quite above the general standard of works published in India; and that the book is well indexed.

SKETCH OF THE HISTORY OF THE MAYO CLINIC AND THE MAYO FOUNDATION. From the Division of Publications. Mayo Clinic, London and Philadelphia: W. B. Saunders Co., Ltd., 1927. Pp. 185. Price, 16s. net.

THE Mayo clinic is at the present time the largest single organisation for the treatment of the sick in

any town in the world. In this little book we have an all too brief sketch of the stages by which it grew from a hospital of forty beds, staffed by the Mayo brothers and their father and with seven sisters of St. Francis as the sole nursing staff, to the present gigantic organisation of over 1,500 beds, occupying several larger hotels built and acquired for the purpose, besides the original hospital, now expanded to 523 beds. The number of patients dealt with annually is about 60,000 and over 23,000 operations are performed, a total which surely surpasses that of any other institution in the world. We are permitted a glimpse of the personality of Dr. W. W. Mayo, one of the pioneers of abdominal surgery in America, but of his two famous sons we learn little, save that the responsibility for the work in the new hospital fell on their shoulders at a time when William J. Mayo had been six years in general practice and his brother Charles H. Mayo had only graduated the previous year. Their father retired from practice about this time and the two brothers carried on at first a large general practice. Neither of them had served as hospital internes, and to use their own expression they felt "the greenest of a green crew," nevertheless, in spite of early local opposition, they made good and within three years of the opening of the hospital they were performing 200 to 300 operations annually. Their reputations were now established and in 1904, fifteen years from the opening of the hospital, they and their assistants performed over 3,000 operations. Associate surgeons, physicians, pathologists and others were added to the staff, until it now numbers 118; the hospital in spite of repeated additions was outgrown by 1907 and the policy of building or taking over hotels to meet the continued expansion was initiated. The clinic building, constructed in 1914 to provide laboratory accommodation, soon proved inadequate for the needs of a service which was increasing by 20 per cent. annually and now the town of Rochester appears to exist mainly by and for the Mayo clinic.

In 1920 the Mayo brothers transferred the whole of the property of the clinic to an association of trustees, surrendering their individual ownership entirely in order to ensure that the clinic shall be perpetuated in its present form. In 1915 the Mayo foundation, supported out of the surplus earnings of the clinic, was established to develop post-graduate medical education and research in association with the University of Minnesota.

Many interesting details of the business management of the clinic, sorting and filing of records, etc., together with complete lists of present and past members of the staff are given, for which the reader must consult the book itself, where he will find the record of a truly remarkable achievement told with becoming modesty.

W. L. H.

HERNIA AND HERNIOPLASTY.—By E. M. Cowell, D.S.O., M.D., F.R.C.S. (Eng.). London: H. K. Lewis and Co., 1927. Pp. xvi plus 128, with 72 illustrations, including 8 plates. Price, 9s. net.

THIS book is written with the avowed object of bringing forward a method of operating on hernias of all kinds by the method of fascial grafting introduced in 1910 by Kirschner, and tested on a large scale experimentally and clinically by Gallie and Lemesurier in 1921. The fact that even in the hands of the most skilled operators the recurrence rate for oblique inguinal hernia is 3 to 8 per cent., for femoral hernia 9 to 14 per cent., and for direct hernia 16 to 25 per cent. shows that there is still room for improvement in the technique of these operations. The author's operation for inguinal and femoral hernia consists in the reinforcement of the abdominal wall by a flap taken from the external oblique aponeurosis, secured in position by a fascial suture from the opposite side of the aponeurosis. The peritoneum at the neck of the sac is separated and excised much more widely

than usual, an important feature of the operation. The technique is somewhat difficult to grasp and the illustrations prepared from photographs of actual operations are not very helpful, but the book is one which should be read by all surgeons, as it breaks new and interesting ground. At the end are two useful appendices by Dr. Otto May on hernia in relation to the Workman's Compensation Act and to life insurance.

W. L. H.

Annual Report.

ANNUAL REPORT, GOVERNMENT GENERAL HOSPITAL, MADRAS, FOR THE YEAR 1926. BY LIEUT.-COL. E. W. C. BRADFIELD, I.M.S., SUPERINTENDENT. MADRAS, SUPERINTENDENT, GOVERNMENT PRINTING, 1927. PRICE RS. 2-12-0.

As usual, this excellent report covers a great deal of ground of professional interest. The number of both out-patients and in-patients gets steadily larger and larger each year, and it is difficult to foresee what is to be done in the way of extra accommodation. The numbers treated in 1926 were 66,154 out-patients and 11,627 in-patients. Total operations numbered 13,294, whilst 232 medical students were under training during the year. On the nursing side there were 10 trained English and Indian sisters, 101 nurses, and 63 probationers. Receipts totalled Rs. 6,84,764, of which no less than Rs. 6,47,257 came from Government grants, whilst hospital recoveries brought in Rs. 36,907. The new Glacia ice plant, recently installed, worked very satisfactorily and saved considerable expenditure. The steam laundry, however, which was installed in 1913 is now very much worn and unsatisfactory. The fire protection is also inadequate.

During the year the services of a Special Manager for the hospital were lent from the Surgeon-General's office, and the office and accounts system were thoroughly overhauled. Colonel Bradfield, however, pleads for more highly paid and more competent supervising and office staff; this is one of the greatest needs of all the big hospitals in the Presidency cities of India.

Turning to the professional side of the report, it is surprising how important is intestinal disease; it was responsible for 1,036 of 9,353 Indian cases admitted; other diseases which rank high are malaria, 684 admissions; diseases of the circulatory system, 498 admissions; and diseases of the organs of locomotion, 633 admissions.

Dr. M. L. Kamanath, Second Physician, draws attention to the prevalence of diphtheria among Indian children in the Madras Presidency. He also records a fatal case of *Bacillus pyocyaneus* septicæmia, and the following case of Hunt's syndrome.

Mr. J., Anglo-Indian male, aged about 50 years, driver, was admitted on 9th February 1926 with ulceration of the left ear and external auditory meatus and left side of neck, facial paralysis, and deafness on the same side. His history was that 15 days previously he had an attack of fever with neuralgic pain in his left ear. Two days after he noticed small vesicular eruptions over his left ear and side of neck; two days later the vesicles burst and formed painful ulcers. A week after his trouble started, he noticed that the left side of the face was paralysed and that he was also short of hearing on the same side. According to James Ramsay Hunt, the pathology is primarily an inflammation of the geniculate ganglion, producing herpetic eruption over the area of distribution of the nervous intermedius. The facial and cochlear nerves being in proximity to the nervous intermedius get involved in the inflammatory process, producing facial paralysis

and deafness. Patient was put on salicylates by mouth, and a bland dusting powder used for the ulcers. Patient got better, and was discharged at request before complete recovery. Blood Wassermann reaction was negative.

Capt. P. N. Basu, I.M.S., Third Physician, records the frequency of hysterical paraplegia and of other forms of hysterical paresis. The following fatal case of jaundice appears to have been of septic origin:—

A Case of Jaundice.—An aged woman of 55 was admitted on 4th September 1926 with intense jaundice, abdominal distension and fullness. The duration of the complaint was two years. Abdominal palpation revealed the margin of the liver 4 fingers below the costal margin. The liver was hard. The spleen was enlarged reaching 3 inches below the costal margin, hard and nodular. Bile pigment and bile acids were present in large quantities in the urine. Albumin and casts were absent. The faeces were large, frothy, with much undigested fat and microscopically there were no ova or cysts. Blood films showed microcytes, macrocytes and normoblasts. There were no parasites. There were hæmorrhages into the substance of the tongue, from the gums, and into the subcutaneous tissues. Coma and death supervened.

Post-mortem.—On autopsy pus was present in the Douglas' pouch. The liver was enlarged, 59 oz., and was softened and yellow. The margins were rounded and the convexity irregular, with bosses. Section showed translucent greyish areas. Spleen weighed 20 oz. Section showed many hæmorrhages resembling infarcts. Pulp was soft, chocolate coloured. Malpighian bodies invisible. The other organs were normal microscopically. The liver showed degeneration and commencing cirrhosis. The spleen showed the appearances of passive venous congestion.

Dr. M. R. Guruswami Mudaliyar Fourth Physician, draws attention to syphilis of the lung, of which condition he records three interesting cases.

Syphilis of the lung.—These cases are not rare and yet there are such few references to these by the profession at large. Some years ago a few cases were reported by me in the hospital report and I had hoped that others might put down their experiences. I am reporting again in the hope that more attention might be drawn to this type of case. Three cases were diagnosed as such this year in my wards.

Case 1.—K, aged 30, male, was admitted on 7th April 1926 with a history of troublesome cough and expectoration with irregular fever of about a year's duration. The patient was ill-nourished and had a fairly large spleen. Liver was not palpable. Right side of chest showed diminished movement, increased tactile fremitus, diminished resonance with high pitched broncho-vesicular breathing. Repeated examinations of the sputum showed pus cells and no tubercular bacilli. The condition was suspected to be due to syphilis as after a year's fairly active disease, if it had been tubercular, cavity formation would have been noticed. Blood was tested for Wassermann reaction and was found strongly positive. A course of N.A.B. cleared up the lung condition and the patient left the hospital on 20th June 1926 cured.

Case 2.—Was interesting inasmuch as he was admitted with high temperature, cough and some paresis of left upper extremity. He gave a history of sudden onset of rigor and fever with paresis of all the extremities about a month prior to admission. The paresis cleared up except in the left upper extremities, about a month prior to admission.

Right lung showed consolidation of the base. There was leucopenia with relative lymphocytosis. Repeated examinations of sputum showed neither tubercle bacilli nor lung tissue. Wassermann reaction was strongly positive. At the time of admission he was in a low condition with hiccup and delirium. With iodides the temperature gradually came down in about a fortnight after admission. Later on a course of N.A.B.

injections cleared up the lung condition and the cough disappeared.

Case 3.—Had a long history of irregular fever, cough and expectoration. Both lungs showed scattered patches of consolidation. Repeated examinations of sputum, and no tubercle bacilli. Wassermann strongly positive. He was started on anti-syphilitic treatment but left the hospital before treatment was completed.

He also draws attention to the use of novarsural in anasarca; its immediate diuretic effect is very marked, but the effect is not lasting. Kyrsgan was used in 8 cases of tuberculosis, three of which definitely improved. He also records the following case of pleural effusion with unusual sequelæ:—

Pleuritic effusion causing kinking of the inferior vena cava and thrombosis of the femoral veins.—P., aged 13 years, was admitted with a history of severe dyspnoea, pain in the side, enlargement of liver, and spleen of four months' duration. Physical examination revealed extensive effusion into left pleural sac, with heart displaced such an extent that the apex beat was half an inch internal to right nipple. Grocco's triangle was well marked and liver and spleen palpable and tender. Immediately after admission 64 ounces of pale straw coloured fluid was withdrawn and by next day the dyspnoea was much less but the pain was no better, specially spleen. Patient was running a temperature and gel was positive in half an hour. Within a week the second tapping was done and still the heart remained on the right side and it was suspected that probably some adhesions were holding the heart in that position and it was feared that femoral thrombosis may develop. Two days after the second tapping patient complained of acute pain in the left iliac fossa. Next day the left leg was swollen and there was tenderness along the course of the left femoral vein. Shortly after the right limb also was involved. The usual symptomatic treatment was adopted. A few days later the left pleural cavity began to fill up again and on tapping was found to contain blood-stained fluid. About this time superficial veins of the abdomen were prominent. A few days later a right-sided pleuritic effusion started, pushed the heart back towards its normal position and the swelling of the leg began to decrease, evidently due to the kink of the inferior vena cava being removed and the venous circulation being made more efficient. After the general condition was improved a good deal the right side was tapped and a pint of blood-stained fluid withdrawn. Later on both sides filled up and the patient collapsed on 3rd February 1926.

Post-mortem.—Careful search for it showed an extensive adherent thrombus extending from below the level of the lower border of the second lumbar spine downwards through the right iliac vein into the right iliac vein.

N.B.—Only the right side was dissected and the left was not opened up. The right femoral vein felt almost like a nerve. The arteries were soft in comparison.

Dr. T. Krishna Menon, Honorary Physician, uses spleen puncture freely in the diagnosis of kala-azar (a change in the former practice at the Madras General Hospital), and has seen no ill effects. He also records the following case of what was apparently black-water fever, or possibly quinine hæmolytic:—

Hæmolytic after Quinine.—K. N., aged 35, Hindu male, resident in Madras city all his life, admitted for fever, headache and vomiting. History of fever with shivering the two previous days and also of similar attacks two months ago. Temperature 104.4, no rigor, headache and pain all over the body, persistent bilious vomiting, abdomen rigid, liver tender and palpable, spleen enlarged 1 inch below costal margin, conscious, but slightly irritable. No other appreciable changes. Blood showed marked leucopenia with mononucleosis. Parasites were not seen even on repeated examination. Urine 1003, acid, clear, no albumin or sugar. Clinically diagnosed as malignant tertian of a pernicious type. Quinine hydrochlor 7½ gr. intravenously and 20 gr.

by mouth in 10 gr. doses was given. The next day conjunctiva was jaundiced, severe pain in the loins was complained of, vomiting (bilious) became incessant. Vandenberg reaction showed biphasic type. Blood examination showed no parasites. Temperature 103°F. The next day temperature came down to 99°F. Urine showed marked changes; became porter coloured with heavy deposit and showed presence of bile and albumin, deposit contained a few R. B. C.'s. Specific gr. 1,020. Quinine was not repeated. Temperature remained normal for four subsequent days. During this time he had occasional vomiting containing blood. Stomach washing showed stale blood. Calcium chloride was given intramuscularly. Adrenalin and hemoplastin were tried. Bloody vomit continued and bleeding was noticed on the gums later. Nervous symptoms grew worse, delirium set in, hiccough and suppression followed 6 days after. As the patient was removed by relatives it was not possible to follow up the case. The interesting feature here is the existence of cases showing hæmolytic after quinine in supposed blackwater fever free areas.

Lieut.-Col. E. W. C. Bradfield, I.M.S., First Surgeon, gives a very interesting table showing the extent of the surgical work done in Madras; 1,085 operations—some of them of a rather severe character—with a total mortality of only 3.94 per cent. In the treatment of burns he has found application of 2.5 per cent. solution of tannic acid and exposure to radiant heat most useful. Mercurochrome has given rather disappointing results in surgical sepsis; but it is useful for irrigation of the bladder. Deep x-ray therapy has recently been used in the treatment of mycetoma. Routine examination of all patients admitted shows that 26.9 per cent. show evidence of syphilis; 20.8 of gonorrhœa; and 9.6 per cent. of both syphilis and gonorrhœa. Since these figures refer to an unselected surgical population, they presumably reflect the incidence in the general population. The figures are decidedly on the high side.

Dr. G. V. James, M.D., C.M., Third Surgeon, records interesting cases of recovery after laparotomy for suppurating tuberculous mesenteric glands, of arthroplasty for osseous ankylosis of the right knee, and of colonic polyposis. A Hindu male patient aged 40 was admitted with a typical picture of amœbic liver abscess; but a few hours after his admission sudden and severe abdominal symptoms set in. The patient's condition was so critical that he could not be operated on till next day, when he was in a less desperate state. On opening the abdomen it was found that a huge liver abscess had burst into the general peritoneal cavity. Appropriate measures and drainage were instituted, and the patient made a most uneventful and quite unexpected recovery.

With regard to gastric and duodenal ulcers, Dr. James writes as follows:—

Gastric and Duodenal Ulcers.—During the year there were 53 operations for the above conditions. In our series also, duodenal ulcers were the most numerous. In almost all the cases posterior vertical "no-loop" anastomosis between the stomach and commencement of the jejunum was carried out. No hæmostatic clamps were used in our operations, all the bleeding points in the cut section of the stomach and jejunum were completely tied with fine catgut before the suturing of their walls was undertaken, and the short time spent on this toilet was considered worth while. The appendix was removed only in those cases where it could be easily delivered out of the upper abdominal wound or when there was any abnormality present. The deaths in our series were almost all due to the supervention of pneumonia after operation. There was no incidence of severe vomiting or hæmorrhage, in this series. Recently in our weaker patients I have been doing this operation under local infiltration anaesthesia and in these cases one special feature was the ease with which the abdominal wall could be closed in layers. There was also a great reduction in the

primary shock even after a prolonged operation, and there was no incidence of pneumonia in these cases. Out of these 53 cases, the appendix was removed in 18 cases.

Capt. T. W. Barnard continued to be Radiologist to the Hospital during the year, and his report shows how continuously this branch of the work continues to expand. The research work on the condition of the pituitary fossa and adjacent sinuses in cases of optic atrophy, in association with the work of Lieut.-Col. R. E. Wright, I.M.S., was continued during the year. The work in the radiant heat and light section was very heavy; whilst the new department for deep therapy was opened during the year.

The staff of this famous old hospital are to be congratulated on yet another year's admirable annual report.

Correspondence.

CHOREA IN INDIANS.

To the Editor, "THE INDIAN MEDICAL GAZETTE."

SIR,—I send the following notes of a case in this hospital as I believe chorea is rare in India, and especially in a patient at this advanced age.

A woman, aged 70, was admitted into the hospital here on October 5th suffering with chorea. She had typical textbook symptoms. She improved rapidly under treatment and left hospital on November 2nd. She was not then quite cured but she was so much better that she insisted on going home. She gave her age as 75, and she was certainly over 65.—Yours, etc.,

B. Z. SHAH, Major, I.M.S.

CIVIL HOSPITAL, NASIK.
19th December 1927.

THE IMPORTANCE OF MEDICO-LEGAL EVIDENCE.

To the Editor, "THE INDIAN MEDICAL GAZETTE."

SIR,—The fact that the following two cases have occurred within one month some time ago in this district shows the importance of medico-legal evidence in cases of suspected murder or homicide.

(1) Two persons started out from home together, and one of them did not return. A body was found hanging from a tree later, and was brought into the station for post-mortem examination, which I carried out. I gave it as my opinion that death was due to suicide. The relatives of the missing man, however, professed to recognise the body, to recognise a photograph and other articles found on it, and pressed for a verdict of homicide. I refused to alter my opinion, however, that death was due to suicide. Two months later the missing man turned up and the body was proved to be that of someone else.

(2) A new born baby was found dead, and post-mortem examination showed that it had been killed, death being due to violence. A midwife and certain other witnesses gave evidence against a certain girl, accusing her of having given birth to the child and having killed it. Counsel for the accused, however, insisted that she should be submitted to a medical examination, when it was found that she was four months pregnant, and therefore could not possibly have given birth to the other child.

Such instances emphasise the importance of medico-legal evidence in cases where other evidence is often entirely unreliable.—Yours, etc.,

RUDRA DUTT, L.M.S.,
Assistant Surgeon.

CIVIL HOSPITAL, MAILSI,
MULTAN DISTRICT, PUNJAB.

GASTRIC AND DUODENAL ULCER.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—The attention of the medical profession in Bengal has been drawn to the method of treatment of gastric and duodenal ulcers by the interesting observations of Major H. Hingston, I.M.S., "on the gastric and duodenal ulcers in Bengal" published in the October 1927 issue of the *Indian Medical Gazette*. Unfortunately we are not in a position to agree with his conclusions until more light is thrown on the subject. Major Hingston seems to think that the medical treatment of the disease is useless and "Surgery seems to be the only hope." The statistics of gastric and duodenal ulcers quoted by Major Hingston do not however show the result of the surgical operations and no mention has been made about the nature of the surgical operation performed and the after result of the cases which have been treated by surgical methods. In the absence of this information, no physician of Bengal, however, is justified in advising surgical treatment of these cases as a routine measure. In the earliest experience of gastric operations, gastro-enterostomy was frequently performed in all the hospitals of Great Britain and Ireland but when the after history of such patients was traced, the results were always indifferent or bad, sometimes lamentable. It will be interesting in this connection to quote the following observations of Sir Berkeley Moynihan in the address recently delivered at the opening of the present session of the King's College Hospital, published in the *British Medical Journal* of 8th October 1927:—

"Perhaps the most abused operation in surgery is gastro-enterostomy. That it is frequently performed when not needed—that it is performed by the clumsy imitator is certain. Many of us have had the bitter duty of undoing such anastomoses or of resecting the ulcer which has developed in consequence of them.

* * * * *

"I conceive that a duty rests upon a physician greater than he realises. When a physician for whose talents and devotion I have great respect, expressed his regret that he could not agree with my advocacy of surgical treatment for chronic incoercible duodenal ulcer because the mortality of the operations was over 10 per cent., I was constrained to say that were the mortality in my hands so high, I should abandon surgery."

There are many instances on record where patients have been operated on for this condition but have derived no permanent benefit. Surgical treatment is of course imperative in cases of perforation or perigastric abscess. Again, ulcers associated with organic pyloric obstruction or organic hour-glass contraction should be operated upon because such cases are not likely to improve under medical treatment. Similarly, surgical treatment may be advised in cases of recurrent hæmorrhage which is not controlled by strict medical treatment. But I am not yet convinced that a physician would be justified in advocating surgery as a routine measure of treatment in every case of gastric or duodenal ulcer.

Major Hingston further observes "In the *mofussil*, I came to the conclusion that the disease was very prevalent among the better classes. In private practice I have seen more of this disease than I have of any other, with the exception of tuberculosis of the lungs." This observation of Major Hingston's however is not supported by the statistics of the hospitals in the Presidency of Bengal, and I doubt whether it will be at all confirmed by other physicians of Bengal who have sufficient clinical experience of this disease.

I admit that a good many cases of gastric or duodenal ulcer with ill-defined symptoms may be overlooked by the average *mofussil* practitioners of Bengal, and that a more careful search and a closer observation of the clinical symptoms and history would undoubtedly lead to the detection of more cases, but such

wide discrepancy between the statistics of Madras and Bengal cannot be explained solely by lack of careful observation on the part of the attending physicians. It will be interesting to note in this connection, that enlarged spleen, dysenteric ulcers, and tubercular foci are very frequently met with in the post-mortem room even in cases where death had been due to other causes. If gastric and duodenal ulcer were very prevalent in Bengal, we should have met with them at least more frequently in the post-mortem rooms attached to the Medical College Hospital, Campbell Hospital, and the police morgue, Calcutta. Again, the relative infrequency of gastric and duodenal perforations and the complications due to them in the surgical wards of the hospitals of Bengal is another argument against the undue prevalence of this disease in Bengal. Not only does the Medical College Hospital of Calcutta show a comparatively lesser incidence of this disease as compared with Madras, but on referring to the statistics of the Campbell Hospital, Calcutta, where poorer patients of all classes are admitted, I find the following figures:—

	1924.	1925.	1926.
Total number of cases of gastric and duodenal ulcers admitted to the medical wards ..	8	13	17

The people of both Bengal and Madras live on rice as their staple food, but the people of Madras are used to take salt, condiments—particularly chillies—in excess, and many of them are vegetarians. Whether their diet, habits and mode of living are responsible for the greater prevalence of gastric and duodenal ulcers in that province is an interesting subject for further investigation.

Major Hingston is of opinion that the ordinary clinical examination, and more particularly the history, is the safest basis on which the diagnosis may be established, and that the complicated pathological, physical, and chemical examinations though of value are not essentially necessary for the proper diagnosis and treatment of this disease. This may be true in well marked cases of advanced type with a history of repeated hæmatemesis and malæna, but when the symptoms of the disease are not very well defined is the physician justified in establishing the diagnosis from clinical symptoms and history alone, when a great authority like Sir Berkeley Moynihan still maintains "Even to-day the diagnosis of gastric ulcer made upon clinical evidence alone is perhaps more often wrong than right." I regret I am therefore not prepared to accept the view of Major Hingston that "a surgeon who considered surgery to be the only cure for these cases would have been perfectly justified in opening the abdomen on the clinical history alone."

Lastly, regarding the efficacy of medical treatment of gastric and duodenal ulcer, I still believe that there is a fair prospect of recovery provided that the disease is diagnosed early and treated properly. A strict watch over the diet and habits of the patient however is essentially necessary for any successful medical treatment. Of course the treatment of duodenal ulcer is easier and less tedious than that of gastric ulcer. I have met with cases of undoubted recovery by medical treatment alone. I know several cases of gastric and duodenal ulcer among the medical practitioners of Calcutta, who have been apparently cured by medical treatment and are still attending to their ordinary avocations in life, not like chronic invalids.—Yours, etc.,

BINOY LALI, MOJUMDER,
Teacher of Medicine and First Physician.

CAMPBELL HOSPITAL,
CALCUTTA,
8th November, 1927.

A CASE OF TRANSPOSED VISCERA.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—An interesting case with transposition of the viscera is under our treatment at the Assam-Bengal

Railway Hospital, Lumding. The patient, an adult male, came complaining of fever and pain in the region of the liver. On examination of what was supposed to be an enlarged and tender liver, it was found that the tumour had a spleen-like notch palpable about two finger-breadths below the right costal margin. On further examination it was found that the heart was situated on the right side, and the liver on the left, the latter being palpable about two finger-breadths below the left costal margin.

On further search for any other abnormalities, it was found that the right radial artery crosses the wrist about an inch and a half above the normal position. No other abnormalities could be detected. Benign tertian malarial parasites were found in blood films from the patient, who is still under treatment for malaria. The patient was shown to Dr. F. C. Lees, Medical Officer, Assam-Bengal Railway, who corroborated the findings.—Yours, etc.,

B. CHATTERJEE, M.B., D.T.M. (Bengal),
Assistant Surgeon.

LUMDING, A.-B. Ry.
28th October 1927.

WHY ARE WE ONE-SIDED?

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—Some time last year I addressed a query to the *Indian Medical Gazette*, asking for information

Now it makes one wonder how we came to stray so far from our original condition, and if the foregoing is correct, it would appear that the long-continued testicular predominance would account for it.

Comparing ourselves again to the lower animals we find that we differ from the mammals, not only in our one-sidedness, but also in the fact that man is the only child of Nature who has forsaken the rule of periodicity in sexual intercourse and I venture to think that in this will be found my answer.

It may be found that the remedy is in the hands of women, and that the modern "freedom for women" movement is progressing unconsciously towards that very goal.—Yours, etc.,

L. V. JANESCH, I.M.D.,
Civil Surgeon.

GONDA, U. P.
20th October, 1927.

THE MILK OF HIMALAYAN COWS. A CORRECTION.

To the Editor, "THE INDIAN MEDICAL GAZETTE."

SIR,—In my article on the "Quality of Milk of Some Special Breeds of Himalayan Cows," which was published in the *Indian Medical Gazette* for October 1927, there were certain misprints. For instance, on p. 557 the following correction should be made.

Breed.	% Total Solids			% Fat.			% Non-fatty solid.			REFERENCE.
	Max.	Min.	Aver.	Max.	Min.	Aver.	Max.	Min.	Aver.	
Hariana (Lucknow)	15.15	11.69	..	6.29	2.94	..	9.42	8.44	..	McMahan. Murray's Chemistry of Dairying.
Germany, Worker-Fleischmann.	12.25	4.30	2.7	3.4	

with regard to the one-sidedness of man, and the causes for this.

I am afraid that I must have expressed myself badly as the two readers who commented upon my query showed that they had "missed the bus."

My chief point was that of all animals, man is the only one-sided one, and that since we were made with two sides to our brains, to use only one showed an evolution that was degenerating. I suggested that there must be a cause for this and that bisymmetrical development might be regulated by an unknown centre.

My query elicited no real information. Perhaps it is of so unimportant and uninteresting a nature, as to awaken no interest in any one else. If so I must apologise for inflicting it again upon your readers, but I must confess that to me it appears of absorbing interest and I can imagine a new genus of supermen arising when man shall have learnt to use his whole body and so revert to, what must be originally our normal state; we have tradition for it that we are not as Heaven originally made us—"In those days giants lived."

I have been reading whatever I could find on the subject and in a publication I recently learned that it has been established that certain internal secretions, notably the testicular, act on the left brain and the right side of the body, and that the pituitary acts on the right brain and the left side of the body. It was further stated that at about the age of 45, the testicular secretion is lessening and the pituitary begins to predominate, and that it is a common experience that at about the age of 45 a man feels less awkward when using his left hand than ever before. This seems to be more than a coincidence.

Yours, etc.,
N. K. ROY.

2, CONVENT LANE,
CALCUTTA,
26th November 1927.

Service Notes.

APPOINTMENTS AND TRANSFERS.

In pursuance of the Provisions of sub-rule (2) of rule 26 of the Council of State Electoral Rules, the Governor-General is pleased to nominate Major-General T. H. Symons, C.S.I., O.B.E., being an official, to be a Member of the said Council of State.

The Viceroy and the Governor-General has been pleased to make the following appointment on His Excellency's personal staff with effect from the date specified:—

To be Honorary Surgeon.

Colonel A. B. Fry, C.I.E., D.S.O., M.D., I.M.S., vice Major-General G. Tate, M.B., K.H.S., I.M.S., vacated. Dated 1st November 1927.

Lieutenant-Colonel J. Anderson, I.M.S., an Agency Surgeon, on return from leave, is posted as Civil Surgeon, Sibi, with effect from the 21st October 1927.

The services of Lieutenant-Colonel G. W. Maconachie, I.M.S., have been placed at the disposal of the Government of Bihar and Orissa, for employment as Officiating Inspector-General of Prisons, Bihar and Orissa,

with effect from the date on which he assumes charge of his duties.

The services of Major R. V. Morrison, M.D., I.M.S., are placed permanently at the disposal of the Government of Burma with effect from 15th July 1925.

On reversion from the cadre of Agency Surgeons under the Government of India in the Foreign and Political Department, the services of Major C. J. Stocker, M.C., I.M.S., are placed temporarily at the disposal of the Government of the Central Provinces, with effect from the 2nd November 1927.

Captain S. D. S. Greval, I.M.S., an Officer of the Medical Research Department, was attached to the Pasteur Institute, Rangoon, as a supernumerary officer from the 7th to the 14th November 1927.

The services of Captain M. T. Khandwalla, I.M.S., are placed temporarily at the disposal of the Government of Madras for employment in the Jail Department with effect from the date on which he assumes charge of his duties.

The services of Captain T. R. Khanna, I.M.S., are placed temporarily at the disposal of the Government of Madras for employment in the Jail Department with effect from the date on which he assumes charge of his duties.

The services of Captain G. H. Fraser, I.M.S., are placed at the disposal of the Government of the United Provinces with effect from the 31st March 1928.

PROMOTION.

In Army Department Notification No. 1172, dated the 24th September 1927, regarding the promotion of Colonels J. D. Graham, C.I.E., M.B., and M. MacKelvie, C.I.E., M.B., F.R.C.S.E., to their present rank, for "6th September 1927" read "8th September 1927."

Lieut.-Colonel to be Colonel.

W. H. C. Forster, M.B., *vice* Colonel A. Fenton, M.B., retired. Dated 25th November 1927.

Bt.-Colonel J. N. Walker, I.M.S., *vice* Colonel K. V. Kukday, C.I.E. Dated 15th September 1927.

The promotion to his present rank of Major J. P. Huban, O.B.E., M.B.E., notified in Army Department Notification No. 1253, dated the 1st October 1926 is antedated from 23rd September 1926 to 23rd March 1926.

Captain (now Major) G. Covell, M.B., I.M.S., is granted the acting rank of Major from 10th December 1918 to 20th December 1919 whilst serving with the British Salonika Force.

Lieutenant J. F. Shepherd, M.B., I.M.S., to be Captain. 1st March 1927. (Substituted for the Notification in the Gazette of 9th September 1927.)

The following *provisional* promotion is made, subject to His Majesty's approval:—

Lieutenant to be Captain.

J. H. Clapp. Dated 15th June 1927.

RETIREMENTS.

Lieutenant-Colonel J. C. H. Leicester, C.I.E., M.D., F.R.C.S., F.R.C.P., V.H.S. Dated 29th September 1927.

Lieutenant-Colonel W. F. Harvey, C.I.E., M.B., I.M.S. 19th October 1927.

Lieutenant-Colonel T. S. Novis, F.R.C.S., V.H.S., I.M.S. Dated 21st November 1927.

Major R. W. G. Hingston, M.C., M.B., I.M.S. From 25th September 1927.

RESIGNATION.

The Governor-General is pleased to accept the resignation by the Hon'ble Major-General A. Hooton, C.I.E., of his office of Member of the Council of State.

NOTES.

LONDON MEDICAL EXHIBITION, 1927.

CENTRAL HALL, WESTMINSTER, ENGLAND,
OCTOBER 3RD TO 7TH, 1927.

Burroughs, Wellcome & Co.'s Exhibit.

IN the Burroughs, Wellcome & Co. exhibit at the London Medical Exhibition one found an impressive array of scientific products of particular interest and service to the medical practitioner.

The causative micro-organisms of such diseases as tetanus, pneumonia, leprosy, syphilis, gonorrhœa, influenza and diphtheria were shown as large, coloured transparencies, and the various medicaments used in the treatment of the diseases were displayed in association. Alternating with the two groups of micrographs there were four panels dealing with the liver, heart, uterus, and nervous system, and the appropriate medicinal agents used in the treatment of pathological conditions of these organs.

Amongst the products which attracted special attention was "Wellcome" Anti-Gas-Gangrene Serum (*B. welchii*). This product, prepared at the Wellcome Physiological Research Laboratories, has given extremely encouraging clinical results in the toxæmia associated with acute intestinal obstruction and peritonitis with ileus.

Three important products for the treatment of leprosy were shown—"Moogrol" a mixture of esters of acids of the chaulmoogric series, "Avenyl" for use in leprosy complicated with syphilis, and "Alepol" which marks another advance in leprology, presenting, as it does, a fraction (low melting point) of the total fatty acids of hydnocarpus oil. Salicin which is of great interest at the moment owing to the fact that it is found to reduce temperature in cases in which quinine, salines and other methods have failed, was presented as "Tabloid" Salicin gr. 5 and 0.25 grammes.

Along with "Ernutin," which presents the essential active principals of ergot of rye in a stable solution and a state of chemical purity, prominence was given to Ergotoxine Ethanesulphonate, a preparation also originated and issued by Burroughs, Wellcome & Co. This new salt is white, crystalline, stable and more soluble than the phosphate, and presents ergotoxine in a purer state than has hitherto been attained.

In view of the increasing importance attached to vitamin-containing products, irradiated ergosterol is of interest in that it offers a method of supplementing "Kepler" Cod-liver Oil in those cases where intensification of treatment is needed. It is prepared by the irradiation of ergosterol with ultra-violet light. Although there is not in practice any proved and well-attested substitute for cod-liver oil, this product is one which may be prescribed in addition to the oil in special cases.

"SUNIC" MEDICAL CARBONS.

THE "Sunic" Medical Carbons have been introduced to meet the demand for standard carbons with a definite zone of ultra-violet emission, and are manufactured by Messrs. Watson and Co., (Electro-Medical), Ltd., Sunic House, 43, Parker Street, Kingsway, London, W. C. 2. They are British made, and the firm claim that they are entirely reliable and are cheaper than foreign carbons. They have been exhaustively tested at the Light Ward of the New End Hospital under the direction of Professor Leonard Hill of the National Institute of Medical Research in Great Britain, and pronounced satisfactory in all respects. They are made in three grades as follows:—

Grade "A."—These are suitable for the radiation of children, where a long exposure with weak intensity of ultra-violet radiation is preferable. These carbons

are somewhat similar to those now widely used and known as "white flame" carbons.

Grade "B."—These are stronger in ultra-violet radiation, and the erythema time is therefore shorter—about 50 per cent. of grade "A." They are especially recommended for adult radiation.

Grade "C."—These are intended for cases where a powerful supply of ultra-violet rays of high penetrative power is required.

The erythema times on a normal skin at 2 ft. 6 ins. from the arc with a direct current voltage of 65–70.30 amperes are

Grade "A"	8 minutes.
Grade "B"	4 minutes.
Grade "C"	3 minutes.

Hitherto the majority of medical carbons have been of foreign manufacture, with inconstant salt content, and as a result of different exposures. The present series should give the radiologist a series of carbons with standard ultra-violet output covering all his requirements.

Having received a consignment of "Sunic" Medical Carbons of "Grade B," packed in the specially devised carton for postage, we made them over to the Radiologist to the Carmichael Hospital for Tropical Diseases, Calcutta, where there is now a recently installed and very complete radiological plant. His report is as follows:—

"I have not had the opportunity to work with the "Sunic" medical carbons long enough to form a definite opinion of them from all points of view. I can however state that I am getting richer ultra-violet radiations, and therefore my erythema dose is shorter with the "Sunic" than with the previous carbons which I have used, which saves a good deal of time. The "Sunic" carbon burns more slowly, and therefore lasts much longer."

PITUITRIN, ITS PURITY AND POTENCY.

THE history of pituitrin and the discovery of its oxytocic action are largely bound up with the firm of Parke Davis and Co., who were the first to render an active extract of the pituitary gland available to the medical profession. Subsequently the drug market of the world has been flooded with numerous brands of pituitrin; some of them reliable, some unreliable. And deviations from the standard are dangerous in dealing with so potent a drug, whether they be deviations in the direction of either weakness or strength. A table recently published by Parke Davis and Co., and quoted below, gives the reported results of assays of samples of pituitrin from eleven different sources; the results are not far short of amazing; thus brand "I" showed a difference of 600 per cent. potency between two packages of the same product.

Competitor.	Assay Based on Pituitrin Standard 100 per cent. Per cent.
A	80
B	50
C	65
D	50
E	125
F	75
G	65
H	50
I	60
J	20
K	20
L	140
M	20
N	less than 5
O	less than 5

Pituitrin can be sterilised by boiling without loss of potency; it possesses remarkable keeping qualities; the injection of Pituitrin is practically painless because, on account of its purity, it does not require an excess

of acid for its preservation; it is free from soluble impurities of the histamine type; the risk of anaphylactic reaction is extremely remote on account of its low protein content; and finally, in colour it is practically water white.

Extraneous matter is of course bound to be present in all such glandular extracts, but Parke Davis and Co. claim—on the basis of assay—that their pituitrin gives an amount of only 1.25 mg. of extractive matter per c.c. as against 4 to 8 mgm. for other brands, and that it has the lowest protein content of any pituitary extract in the market. Also that it can be sterilised by boiling; that it keeps well; that it is free from impurities of the histamine type, which might bring about shock; and that its injection is practically painless, as it does not require an excess of acid for its preservation.

The firm of Parke Davis and Co. have been so long especially associated with pituitary extracts that they may well claim that their product is a reliable one.

B. W. & CO'S INSULIN.

WE have received the following letter from Messrs. Burroughs, Wellcome & Co., which we publish with pleasure.

To

The Editor,
The Indian Medical Gazette,
Calcutta.

Dear Sir,

In the July issue of the *Gazette* you were so kind as to print a little notice in regard to the two strengths of Wellcome Brand Insulin now available, in which notice the prices were quoted as they appeared in our memo. of the 20th April. Unfortunately, the rates were reduced some time after we had written to you and before the July issue of the *Gazette* appeared.

The rates now current in Bombay are:

Per phial of 100 units	..	Rs. 2-8.
Per phial of 200 units	..	Rs. 5.

If you can very kindly agree to permitting the notice to appear again in the next issue of the *Indian Medical Gazette*, with the reduced prices mentioned above, it will help to remove an awkward impression.

We thank you in anticipation.

Yours respectfully,

BURROUGHS, WELLCOME & CO.

21st September 1927.

Publishers' Notice.

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles will receive 25 reprints *gratis*, if asked for at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE Editor, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions, Advertisements, and Reprints should be addressed to THE PUBLISHERS, Messrs. Thacker, Spink & Co., P. O. Box No. 54, Calcutta.

Annual Subscription to "*The Indian Medical Gazette*," Rs. 16 including postage, in India. Rs. 18 including postage, abroad.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

BY APPOINTMENT TO
H.R.H. THE PRINCE OF WALES

KOLYNOS DENTAL CREAM

VARIOUS devices have been offered as a means of disinfecting tooth-brushes; none, however, have enjoyed wide acceptance. Bearing directly upon this important subject is the work of W. Parker Harrison, M.R.C.S., L.R.C.P., L.D.S., who, as a result of studying the influence of dental creams upon septic conditions of the toothbrush, has found that:—

1. A dental cream is an important factor in the sanitary state of the toothbrush.
2. An antiseptic dental cream will greatly reduce the number of bacteria present.

A recent investigation in which Kolynos Dental Cream was employed gave these striking figures:—

Number of Bacteria Present on Toothbrush.			
After	5 Minutes	1 Hour	6 Hours
Brush only	2,387,000	2,184,000	330,000
Brush with Kolynos	15,000	10,000	6,400

These results clearly indicate that very few bacteria were present on the brush when used with Kolynos Dental Cream, which thoroughly cleans the oral cavity and without additional effort by the user, keeps the toothbrush in a wholesome, sanitary condition.

On request our Distributors will gladly send you a dental package, free of charge.

Cardiazol «Knoll»

(Pentamethylentetrazol)

a fundamentally new analeptic

without the unpleasant properties
of camphor, absolutely
water-soluble and of

surprisingly rapid action

(subcutaneously after 5—6 minutes).

Subcutaneous application painless. No cumulative action even though given daily and hourly during protracted periods. Powerful effect on respiration. No cerebral disturbances or other undesirable phenomena. The effect of Cardiazol administered orally is more protracted than that of subcutaneous injection.

SOME LABORATORY FINDINGS AND THEIR SIGNIFICANCE.

By J. W. D. MEGAW, C.I.E.,

Lt.-Col. I.M.S.,

Director and Professor of Tropical Medicine, Calcutta
School of Tropical Medicine

and

M. N. MULLICK, M.B.,

Registrar, Carmichael Hospital for Tropical Diseases,
Calcutta.

THIS note deals with the laboratory findings in 400 unselected patients of the Hospital of the Calcutta School of Tropical Medicine and Hygiene.

The laboratory examinations were made in the research departments of the School, so that the greater part of the work which was involved is to be credited to Lt.-Col. Acton, Lt.-Col. Knowles, Major Lloyd and Dr. Sundar Rao. The analysis of the findings was made under the direction of the senior author by Dr. Mullick, the Registrar of the Hospital.

All the patients who are admitted to the beds of the hospital which are under the senior writer's charge are subjected to a number of routine examinations, irrespective of the disease from which they are supposed to be suffering.

The reasons for this practice are (a) that it is often impossible to detect the existence of certain diseases by clinical examination only, so that these diseases will often be overlooked unless every available means of diagnosis is employed: this is specially true of syphilis which often occurs, either alone or with some other disease, in a latent form, so that neither history nor physical signs may give the slightest clue to its presence. It is well known that the patient in the tropics seldom suffers from only one disease; usually there are two or more co-existing diseases each of which has to be treated, if restoration to health is to be brought about. Some people regard these routine examinations as being unnecessary; they think that those who fall back on them must be devoid of diagnostic acumen: if this be true a frank confession of lack of skill must be made by the senior writer, for there has seldom been a patient under his charge in whose case help has not been obtained from the laboratory examinations. This help may be positive or negative; in either case it conduces to accuracy of diagnosis.

(b) An equally important reason for routine examinations is that we cannot form a true estimate of the significance of laboratory findings unless we have controls. When examinations are made only in patients who are suspected to have a disease we remain ignorant of the normal standards; serious errors have arisen in this

way, for example kala-azar at various times was believed to be malaria, hookworm disease, and even undulant fever, merely because of the absence of controls in connection with the laboratory findings. This note represents a preliminary attempt to discover the degree of weight which is to be attached to certain laboratory reports.

The examinations have been made under favourable conditions in laboratories under the charge of experts, but they were carried out in a routine manner and may be regarded as representative of what occurs in every-day practice.

Unfortunately it is impossible to carry out a complete series of laboratory examinations in each patient who is dealt with in hospital or private practice, but for this very reason it is all the more important that medical men should know the likelihood of occurrence of the important diseases in latent form and also the degree of weight which they can attach to laboratory findings when they are made.

It is probably true that laboratory reports mislead the practitioner nearly as often as they help him: this is not the fault of the reports, but of their interpretation, and it is necessary to lay great emphasis on the importance of a full consultation between the laboratory expert and the physician.

The Significance of Agglutination Reactions Against Flexner Bacilli.

In Calcutta and many places in Bengal, dysentery rarely occurs as a severe fatal disease. In this hospital comparatively few cases of acute dysentery were treated, and in an investigation of the bowel diseases of the Asansol Mining area Capt. Maitra, I.M.S., of this School found that dysentery was not an important factor in causing death or loss of efficiency among the mining population.

On the other hand dysentery may be an exceedingly severe disease in times of famine or war, among pilgrims who are subjected to great hardship, and occasionally in jails, as for example among the Moplah prisoners in Alipuram jail, Bellary, as reported by V. J. Lopez in the *Indian Medical Gazette*, December 1926, p. 590.

It has come to us as a surprise that dysentery under normal conditions in India is so mild a disease: we all know how terribly fatal it can be when people are crowded together under insanitary conditions; especially when the persons concerned are of low vitality and unsuitably fed.

Flexner Agglutination Tests.

In estimating the significance of these results it must be remembered that while mild bacillary dysentery is common in Calcutta the severe forms of the disease are rare. The *Entamoeba histolytica* was rarely found as a complicating factor, cases in which it occurred have been excluded from the series.

(1) The higher proportion of positives among those who have had recent dysentery as

Analysis of Agglutination Response to the Flexner Bacillus in 400 Patients.

Titre.	Total number.	Actual signs of dysentery.	No dysentery, but history of dysentery within previous three months.	Dysentery more than three months ago.	No history of dysentery.	Flexner bacilli isolated.
+ $\frac{1}{160}$	50	13 (26%)	2 (4%)	15 (30%)	20 (40%)	2 (a)
+ $\frac{1}{20}$ to + $\frac{1}{80}$	153	22 (14.4%)	8 (5.2%)	38 (24.8%)	85 (55.5%)	2 (b)
Negative ..	197	17 (8.7%)	3 (1.5%)	22 (11.1%)	155 (78.7%)	2 (c)

(a) Both of these were suffering from dysentery.

(b) One of these had dysentery; the other gave no history of dysentery or diarrhoea and showed no signs of diarrhoea or dysentery.

(c) One had dysentery; the other gave no history of dysentery or diarrhoea, and showed no signs of bowel disorder.

Agglutination against Shiga Bacillus in 400 unselected patients.

Titre.	Total number.	Actual signs of dysentery present.	No dysentery, but history of dysentery within previous three months.	Dysentery more than three months ago.	No history of dysentery.	Shiga bacilli isolated.
+ $\frac{1}{160}$	1	0	0	1	0	0
+ $\frac{1}{20}$ to + $\frac{1}{80}$	66	10 (15.1%)	5 (7.5%)	18 (27.2%)	33 (50%)	0

(a) 11 gave a history of diarrhoea.

compared with those who are not aware that they have suffered from the disease suggests rather strongly that a positive reaction is evidence in favour of the previous occurrence of an infection by one of the bacilli of dysentery: if diarrhoea be included among the manifestations of the activity of the bacilli of dysentery the case becomes even stronger; and it is reasonable to assume from the findings (a) that infection with the bacilli of dysentery is very common and widespread in Calcutta; (b) that this seldom gives rise to severe dysentery; (c) that some degree of immunity due to previous invasions is common; and (d) that the Flexner type of organism is the prevailing one.

(2) A positive finding, especially in low dilutions, is so common that it cannot be accepted as weighty evidence that an existing attack of dysentery is due to the bacillus which is agglutinated. A series of tests showing the variation in the agglutinin curve would probably be of value in acute cases, but such cases are not included in the series.

(3) A negative finding does not exclude the existence of infection. Among the negatives there were two cases in which Flexner bacilli were isolated from the stools; one of these gave no history of dysentery.

(4) Six carriers of bacillary dysentery were found by the routine examination among 400 unselected cases, and it is very likely that a larger number would have been found if repeated examinations of perfectly fresh stools had been made.

(5) Agglutination tests cannot be relied on for the discovery of carriers of the bacilli of dysentery.

Agglutinins Against the Shiga Bacillus.

(1) This type of organism was not isolated from any of the 400 stools examined in a routine manner.

(2) The absence of carriers and the rarity of high titre agglutination suggest that Shiga bacilli are uncommon in Calcutta, or alternatively that agglutinins disappear rapidly and that carriers of Shiga infection are rare in this part of India.

The Widal Reaction.

It is to be noted that single routine tests only are dealt with. It is certain that repeated tests made in accordance with the Dreyer technique would have given far more information, but as the usual procedure among practitioners is to have one or two tests made it was considered

Widal Response in 400 Unselected Cases. (1) Typhoid.

Titre.	Number.	Typhoid diagnosed on clinical grounds.	History of typhoid during the past year.		History of typhoid more than a year ago.		No history of typhoid or inoculation.

advisable to analyse the results of a single routine test, which was made soon after the admission of the patient. The following points may be noted:—

(1) The outstanding feature of this series is that positive Widal reactions in fairly high dilutions are so common in persons who are not suffering from the disease that they are of little value as evidence of the existence of the disease, even in persons who have never been inoculated. This statement has special reference to persons who have lived in Bengal; it may not be true of people living in Europe.

(2) The findings are very suggestive of the existence of widespread infection of the population in childhood, and also of the existence of a considerable degree of immunity resulting from these attacks.

(3) The fact that typhoid bacilli have not been isolated from any of the 400 stools is not strongly stressed; it is not claimed that there are no carriers among the 400 persons who were dealt with; a much more elaborate investigation would be needed before this position could be taken up.

(4) The frequency of vague histories of previous attacks of continued fever among the positives as compared with the negatives suggests that many of these attacks were really typhoid fever which was not recognized.

The question of typhoid infection in childhood in India needs further study. There is rather strong presumptive evidence that most of the

children in the large centres of population suffer at some time from typhoid fever.

The para-typhoid groups do not call for much comment: in most cases the agglutinins were associated with agglutinins against typhoid bacilli.

Cysts of *Entamæba histolytica* in 100 Unselected Cases.

	Actual dysentery.	Dysentery within previous three months.	Dysentery more than three months ago.	History of diarrhoea.	No history of diarrhoea or dysentery.
Positive 7 (7%) ..	1	1	3	1	1
Negative 93 (93%)

Entamæba histolytica Infections.

It is remarkable that vegetative forms were not found in any of 100 unselected patients, and cysts only in 7. Doubtless repeated and prolonged examinations would give very different results but it is clear that amœbic dysentery does not loom large among the unselected population of Calcutta.

Out of the 7 patients who harboured cysts, 5 gave a history of previous dysentery and one of diarrhoea.

Wassermann Reactions in 400 Unselected Patients.

Of these 90 were kala-azar patients.

Strongly positive	25	6.25%
Moderately positive	76	19%
Doubtful	34	8.5%
Negative	265	66.25%

Wassermann Reactions in 310 Non-kala-azar and 90 Kala-azar Patients.

	(a) 310 non kala-azar patients.	(b) 90 with kala-azar.
Strongly positive ..	19 (6.1%)	6 (6.7%)
Moderately positive	51 (16.4%)	25 (27.7%)
Doubtful	27 (8.7%)	15 (16.6%)
Negative ..	213 (68.7%)	44 (48.9%)
	310 (100%)	90 (100%)

The Wassermann test has been found to be less misleading than any of the other tests which have been applied; it has also been more helpful in clearing up the real nature of obscure disease conditions.

The patients in whom a positive reaction was found were not admitted for syphilis and in most cases their symptoms were due to some other disease, but it has repeatedly happened that a restoration to health was not brought about by treatment of the disease for which the patient was treated until a course of anti-syphilitic treatment was carried out.

There was one dramatic case in which the patient suffered from cerebro-spinal meningitis; the diplococcus was found by lumbar puncture and treatment with Flexner's serum gave good results up to a certain point. After a few days the patient sank into a condition of coma and it was obvious that recovery could not be hoped for. At this stage the patient came under my care and a routine series of tests was carried out; the Wassermann reaction was reported to be strongly positive. Neosalvarsan was injected with results which were little short of miraculous, and in a few days the patient was walking about the ward.

Other cases could be recorded in which the Wassermann test supplied the clue to riddles which would otherwise have been insoluble, and the results of treatment left no room for doubt as to the correctness of the solution.

The time will come when a Wassermann test will be regarded as an essential routine method of diagnosis, and it is to be hoped that a simple

and reliable test will soon be available to the clinician.

The high proportion of positive findings in cases of kala-azar is capable of two interpretations:

(1) that the blood changes in the disease accentuate the serological conditions which are responsible for the positive Wassermann findings, or (2) that the presence of the syphilitic virus predisposes to the occurrence of kala-azar.

There are grounds for believing that lowered resistance is an important factor in predisposing to kala-azar, and it is quite possible that syphilis may be one of the causes of the lowering of resistance to the disease.

Microfilaria bancrofti Infection in 400 Unselected Cases.

	No evidence of filarial disease.	Doubtful evidence of filarial disease. (a)	Lymphangitis, probably filarial.
Positive 27 (6.75%) ..	18 (66.7%)	6 (22.2%)	3 (11.1%)
Negative 373 (93.25%)

(a) History of periodical attacks of fever with shivering.

Microfilaria bancrofti infection in 87 cases of lymphangitis believed to be filarial.

Positive ..	11 (12.6%)
Negative ..	76 (87.3%)

*Microfilaria bancrofti in 7 cases of chyluria.**

Positive ..	7 (100%)
Negative ..	0 (0%)

* These figures were kindly supplied by Dr. Sundar Rao, the Darbhanga Research Scholar in Filariasis.

Microfilarial Infection.

Among 400 unselected patients, mostly from Calcutta, microfilaria were found in 27. Of these 23 were residents of Calcutta, one of Allahabad, one of Nadia District, one of the 24-Parganas, and one of Midnapore. Only nine of these gave any evidence which might be construed as pointing to the existence of symptoms of filariasis; two had suffered from lymphangitis, and seven from occasional attacks of fever with rigors which might or might not be associated with the filarial invasion; none of the seven showed evidence of the existence of any disease which could be attributed with certainty to filarial infestation.

These facts are not brought forward as evidence that there is no association between filarial infestation and the various forms of "filariasis." We believe that such association exists, though it is not necessarily direct, but is more probably the result of a secondary infection which would not have caused disease manifestations but for the presence of the filarial parasite,

What must be emphasized is (1) that the finding of microfilariae cannot in itself be regarded as evidence that disease symptoms which occur are caused by the filariae.

(2) Equally the failure to find microfilariae in the blood is not evidence that symptoms are not associated with filarial invasion.

In the patients admitted for lymphangitis, presumably of filarial origin, the microfilariae are usually absent.

General Observations.

Detailed analyses have not been made in connection with such routine examinations as those for hookworm and other ova, malarial parasites, aldehyde tests, etc., as these can best be dealt with by the specialists concerned.

Hookworm ova are found in about 27.6 per cent. of unselected cases in Calcutta, but it is only in a small proportion of the positives that the infection appears to be important.

Malarial parasites are frequently absent or missed in cases of malaria, and the clinician who always refuses to give quinine until parasites are found does not act in the best interests of his patients.

Blood cultures have been made in all doubtful cases of fever, but the positive findings have been so few that analysis is hardly worth while.

Total and differential leucocyte counts are also made as a matter of routine and are of great value in diagnosis, but there is little to add to the work of Sir Leonard Rogers and others on this subject. Stress may again be laid on the frequency with which a moderate leucocytosis without great increase in the polymorphonuclears is the only clue to the existence of amœbiasis. Several patients have had an unexplained intermittent fever with no symptoms suggestive of liver trouble; no evidence of *E. histolytica* infection could be found and the cause of the fever could only be discovered by carrying out the "emetine test." In one of these cases the leucocyte count was hardly above the normal limit, but the response to emetine was so prompt as to leave little room for doubt as to the nature of the disease.

This aldehyde test is of special value in cases of unexplained chronic fever with enlarged spleen, but cases are occasionally met with in which all the resources of the modern laboratory fail to discover evidence of kala-azar or malaria, which nevertheless respond to antimony or quinine.

Even in this stronghold of the laboratory experts the clinician still has his uses; in ordinary circumstances he must be encouraged to "keep his end up" while making the utmost use of his allies in the laboratory.

Conclusions.

From the results which have been summarized it is obvious that clinical laboratory tests are often useless or misleading unless they are interpreted correctly. They often indicate the

presence of a previous infection or of an existing infection which may not be the cause of the patient's illness.

If they are regarded as a final court of appeal the judgment which is based on them will often be wrong; therefore, it is necessary for the laboratory worker and the clinician to work in consultation with each other, and it will usually be necessary for the clinician to form the final judgment as to the part which is played by any infection which is revealed in the laboratory.

A positive Wassermann reaction is a call for anti-syphilitic treatment, either immediately or after the subsidence of the other disease for which the patient is being treated. When possible it is desirable that a series of routine laboratory examinations should be made in the case of every patient, as it is only in this way that a true estimate can be made of the significance of laboratory findings.

ANÆSTHESIA OF THE SPLANCHNIC AREA IN THE SURGERY OF THE UPPER ABDOMEN.

By H. E. MURRAY, M.B., B.Ch. (T.C.D.),

MAJOR I.M.S.,

First Resident Surgeon, Presidency General Hospital, Calcutta.

DURING September, 1927, notes on the technique of splanchnic anæsthesia were received in the Presidency General Hospital, and it was decided that it should be given a trial.

So far this procedure has been adopted in 12 cases and the results have been so strikingly good that I consider a description of the technique for publication would be of great benefit to those who up to now are not in possession of it.

Those who practise the surgery of the upper abdomen, and have not the advantage of a skilled anæsthetist, are only too well aware of the difficulties, and annoyances, due to bad administration of a general anæsthetic, which may be met with when operating on this area of the abdomen.

The picture of a surgeon who has set out to perform a cholecystectomy, or gastro-enterostomy, and who, on opening the abdomen has to wait many minutes before he can proceed, and perhaps may even have to hold the intestines in their place with his hands, while the patient coughs, strains, and endeavours to empty the abdominal contents on to the operation sheet, is only too familiar.

Later, the operation may be hindered and delayed by the anæsthetist failing to keep the patient "under," with the result that the packed off intestines creep round the packs into the operation area.

Anæsthesia of the splanchnic area will obviate all this, and the few minutes taken in its performance before the operation proper is begun is time well spent.

Within two or three minutes of injecting the novocaine the patient is breathing without distress; there is no protrusion of the intestines into the operation area, or out of the abdomen, and the amount of general anæsthetic required is considerably lessened.

The technique is as follows:—

Two strengths of novocaine are used.

$\frac{1}{2}$ per cent. solution and 1 per cent. solution.

In the Presidency General Hospital, a 50 c.c. syringe, and a 30 c.c. syringe are employed, and in all 100 c.c. of $\frac{1}{2}$ per cent. solution are used for the first step, and 30 c.c. of the 1 per cent. solution are used for the second step.

The actual size of the syringe of course does not matter, but it is easier to work with a big one.

The patient is prepared, and the anæsthetist starts off the general anæsthetic in the usual manner.

When the surgeon is washed up, he fills the 50 c.c. syringe with the $\frac{1}{2}$ per cent. solution of novocaine, and determines the lowest point of the costal arch on one or other side.

The needle is inserted into the skin and deeper tissues till it is felt to strike the rib, and later the costal cartilage. When the rib or cartilage is felt on the point of the needle the latter is depressed and entered for a short distance under the costal arch. Some of the solution is then forced out into the tissues immediately surrounding the intercostal nerve. The needle is then withdrawn, inserted a little higher up the costal arch, and some more solution forced out, and so on until the ensiform cartilage is reached, when the opposite costal arch is similarly treated.

The abdomen is then opened by whatever incision in the upper abdomen is practised by the operator. The line of incision is not infiltrated.

The 30 c.c. syringe by this time has been filled with 1 per cent. solution of novocaine by the assistant and is held in readiness by him, or is placed close to the operator's right hand.

When the abdomen is opened, the lesser curvature of the stomach is determined and the fingers of the left hand introduced above it until the body of the 1st lumbar vertebra is felt, just above and to the right of the origin of the coeliac axis.

The index and middle fingers of the left hand are then slightly separated. This pushes the aorta further to the left, and leaves an area devoid of blood vessels on the body of the vertebra between the separated fingers. The needle is then introduced into this space and pushed home till it impinges on the body of the vertebra.

The syringe is now attached to the needle and the 30 c.c. of 1 per cent. solution is injected at a fairly slow rate. Care must be taken not to puncture a blood vessel, but if this should happen the needle must be removed and inserted in another place.

This accident has not occurred in any of the 12 cases in the series, which proves that if the

technique is correctly carried out there is not any great likelihood of injuring a vessel.

It was found in the first two cases that there was some difficulty in attaching the 30 c.c. syringe to the needle when *in situ*, as a needle of 6 or 7 inches was really required to reach from the vertebra to the surface of the abdominal wall.

This difficulty was got over by attaching 6 inches of rubber tubing to the needle before it is inserted, and at the other end firmly fixing a metal connection which fits the syringe. There is a glass window in the length of tubing, which will enable the operator to see if a vessel has been injured.

The needle is then withdrawn, and the operation proper proceeded with.

The technique is simple, its result a boon to surgeons, and no ill after-effects have been observed in these 12 cases.

On two occasions the patients breathed very slowly, and seemed as if they would stop breathing altogether, but there was no dyspnoea, and no cyanosis, and the breathing gradually came back to normal rate without any interference.

The amount of 1 per cent. novocaine was then lessened from 50 c.c. (which was used at first) to 30 c.c. and this phenomenon has not happened since.

My thanks are due to Lt.-Col. A. H. Proctor, M.D., F.R.C.S. (Edin.), I.M.S., for the elaboration of the above technique, and the starting of its practice in the Presidency General Hospital; also to Major H. G. Alexander, F.R.C.S., I.M.S., for its very clear description which he wrote out from England.

AN INTRA-ABDOMINAL OPERATION FOR OBLIQUE INGUINAL HERNIA.

By P. BANERJEE,

MAJOR I.M.S.,

Resident Surgeon, Medical College Hospitals, Calcutta.

OPERATIONS devised for the radical cure of hernia are many. From the simplest one devised by Banks to the most elaborate one practised by Bassini a great deal of ingenuity has been shown by the originators of the various methods. At present there are two theories as to the cause of oblique inguinal hernia, namely the theory of Hamilton Russell and others, who think that the majority of oblique inguinal hernias descend into patent vaginal processes and that "acquired oblique inguinal hernia in the young subject has probably no existence in fact." They believe that the vast majority of all oblique inguinal hernias are due to the presence of congenital sacs. The average worked out from observations of several authorities showed that in normal children 59 per cent. had patent peritoneo-vaginal processes during the first four months and 44 per cent. even during the fifth month. Further, in children with hernia over 80 per cent. had unobliterated vaginal processes.

Others think that excepting in children such hernias in adults are caused by strain on an

abdominal wall weakened at its vulnerable points. It is certain, however, that to have a hernia, acquired or congenital, there should be a weak spot in the abdominal wall and an increase of intra-abdominal pressure. Of the many weak points on the abdominal wall the region of the inguinal canal is one. The increase of intra-abdominal pressure may be rapidly developed or may be of intermittent character or caused by a single sudden powerful strain. These are the two factors which are believed to cause all hernias, except those which are present at birth. Where the peritoneal processus vaginalis persists unobliterated, descent of the hernia is extremely easy, but where there is no pre-formed sac the increase of intra-abdominal pressure required to bring it about must be considerable and the descent is slower, gradual and occurs later in life. There are of course exceptions in both classes of cases. Even where there is no peritoneal sac, the peritoneum forms a marked dimple at the internal abdominal ring viewed from inside due to its adhesion at that point to the cord as it passes down.

The object of Bassini's operation is twofold namely, (i) removal of the sac and closing its opening at the internal abdominal ring and (ii) strengthening of the abdominal wall in the region of the canal. Those who believe in the theory of preformed sacs are quite satisfied with removing the sac and closing the neck, i.e., the opening at the internal abdominal ring; while those who think that hernias are caused by an acquired or inherited weakness of the abdominal wall, which permits a process of peritoneum to be pushed out through the canal perform Bassini's operation or some modification of it.

The causes of recurrence of hernia are (1) incomplete removal of the sac, (2) considerable and permanent weakening of the abdominal wall in old subjects, (3) suppuration, which may have been caused by faulty technique or neglect carefully to stop all hæmorrhages, which, if allowed to persist, lead to formation of hæmatoma and sepsis, and (4) post-operative vomiting or coughing which causes the ligatures to tear through the tissues.

Statistics regarding recurrence in the two types of operation show that there is nothing to choose between either form of operation.

I consider that these extra-abdominal methods of dealing with inguinal hernia, however ingenious they may be, especially those in which an attempt is made to strengthen the canal and to fix the stump left after removal of the sac, are clumsy and unreliable. It is doubtful if it is possible to strengthen the canal effectively by any method. Union between muscle and ligament must be fibrous and weak and in an individual with a very lax and weak abdominal wall and in whom the exciting cause, which is possibly an intermittent increase of intra-abdominal pressure, persists, it will surely give way. Even the effort of coughing or vomiting immediately after the

operation will tear the muscle apart from ligament or loosen the ligatures.

Further, dissection in the admittedly weak inguinal region, and mutilation of tissues caused in separating the cord from the sac and the sac from its coverings are very harmful. Thus, pain and hyperæsthesia over the cicatrix due to inclusion of nerves in ligatures, (2) atrophy of the testis due to injury to the vas, spermatic artery, or owing to pressure of a tightly sutured canal wall, (3) formation of a varicocele due also to tight suturing, (4) torsion of the testis due to twisting the gland during manipulation, (5) orchitis and epididymitis, results of rough handling of the vas or due to congestion of the pampiniform plexus, are not uncommon complications after Bassini's operation for radical cure of hernia. Besides repair of mutilated tissues by scar tissue always leaves them weaker than before.

Any attempt to obliterate the sac completely from outside must be defective because beyond the internal abdominal ring *there may be and often is* lax posterior parietal peritoneum ready to be forced out or descend. It is often the case that increase in size of a hernial sac however it may have originated is effected at the expense of the posterior parietal peritoneum. The chief cause of recurrence to my mind is this incomplete removal of the sac. It is impossible by any operation in which we approach the sac from without so to remove it as not to leave the so-called dimple which may at any time form the nucleus of a fresh hernia.

Fixing the neck of the sac to the anterior abdominal wall has the disadvantage of weakening the abdominal wall where the stump is fixed, and where recurrence often takes place, as the ligature strangles the muscle fibres at the site, and replaces it by fibrous tissue. Further, it does not strengthen or obliterate the loose parietal peritoneum.

It seems to me therefore that the factors in the operation, which should be depended on most to prevent recurrence, are the careful obliteration of the opening in the sac and tightening up of the loose parietal peritoneum round it, and these can be effected only by an intra-abdominal operation, which is a far more simple operation than the present extra-abdominal ones. The terrors of opening the abdomen are past. In any case, the abdominal cavity has to be entered whatever operation is performed. The method I have practised in these cases is so simple and—to my mind—so efficient that I will take the liberty of describing it now in the hope that it may find favour with some surgeons and may be given a thorough trial. In this operation not only is the inner opening completely closed without leaving a dimple, but in the process three layers of peritoneum are superimposed over the point where the opening existed leaving the canal quite unaffected and intact. Loose folds of parietal peritoneum are also tightened. There is no manipulation or separation of the delicate

constituents of the cord from the sac and therefore no damage to them. The sac itself is not handled and being serous in structure and when no longer kept open by abdominal contents is later obliterated by adhesions of its walls or atrophy or both.

Operation.—The bladder should be carefully emptied and a three to four inch paramedian incision made either on the left or on the right side according to the situation of the hernia. The skin incision is made very close to the middle line commencing from half an inch above the pubic crest and extending perpendicularly upwards. The anterior sheath is incised about a quarter of an inch from the middle line and the rectus muscle retracted outwards. The transversalis fascia, extra-peritoneal fat and peritoneum are then incised and their edges picked up together by forceps everted and retracted. A warm towel is then introduced into the abdominal cavity and the intestines kept away from the inguinal ligament and the internal abdominal ring, which is found about two inches to the outer side of the middle line. The finger may now be introduced through the internal abdominal ring into the hernial sac to demonstrate it.

Pick up with four or five forceps the peritoneum from the circumference of the ring a quarter of an inch away from its margin, being careful to avoid lifting up the cord. The circular fold of peritoneum thus lifted up is now closed by a purse-string suture of fine catgut. This suture is then covered by peritoneum picked up either by interrupted or continuous Lembert stitches from the surrounding loose parietal peritoneum. Thus not only is the opening of the sac most efficiently obliterated but the loose peritoneal folds lying immediately around it are utilized to strengthen the closure. A Lembert suture as mentioned provides a covering of two layers of peritoneum above the purse-string suture. The abdomen is now closed in layers. The operation is practically bloodless, efficient and quick. It can, however, only be done in cases of reducible hernia. The operation may be performed under novocain infiltration anæsthesia, supplemented if necessary by a few whiffs of ether.

A NOTE ON THE VALUE OF RECTAL INJECTIONS OF POTASSIUM PERMANGANATE IN THE TREATMENT OF PNEUMONIA.

By A. BAYLEY DE CASTRO.

Lieut., I.M.D.,

Junior Medical Officer, Port Blair, Andamans.

IN the *British Medical Journal* for July 17th, 1926, there appeared an article by Dr. Herbert W. Nott of Little Sutton, Birkenhead, on the value of rectal injections of potassium permanganate solution in the treatment of pneumonia. His technique is slow rectal injection of a warm solution of potassium permanganate of

strength 2 grains to the pint, in quantities of from 4 ozs. to one pint, three to four times a day. He further states '...no one knows why potassium permanganate held in aqueous solution and injected into the rectum, should give such good results.'

Since reading his article, and at the suggestion of Major J. M. R. Hennessy, I.M.S., Senior Medical Officer, Port Blair, I have given this treatment a trial, and make these notes on the results obtained.

I began the treatment on the 9th September, 1926, and from that date up to March 21st, 1927, have treated twenty-two cases, with 50 per cent. of recoveries. At first sight this recovery rate may appear to be a very poor one, but it should be understood that our patients are usually very debilitated, that pneumonia among them in Port Blair is apt to prove an extremely fatal disease, and that it is only in the few patients who come to hospital at the earliest indications of disease that it runs a comparatively mild course. The majority of cases come to hospital late in the disease, and have probably carried on their work until the second or third day of illness.

The salient features observed with this line of treatment were:

- (1) The rapid disappearance of respiratory discomfort.
- (2) The early fall in temperature.
- (3) The early commencement of expectoration.
- (4) The ease with which expectoration is performed.
- (5) The improvement in appearance and well-being of the patient.

After each injection there is a drop of about one degree in the temperature for from half an hour to an hour, and it was always noted that 24 to 36 hours after starting treatment there was fairly free expectoration. The sputum had a yellowish tinge, and did not have the tenaciousness so characteristic of the sputum in lobar pneumonia.

There is also a marked controlling effect on the pyrexia, as will be seen from the temperature charts, and this good effect was seen even in cases of massive pneumonia of the lungs; e.g., Case No. 6.

In Port Blair, although pneumonia is not a very important cause of admissions to hospital, yet the cases which we get are almost always of very severe type; frequently too the patients are long standing sufferers from chronic malaria; and under these circumstances a 50 per cent. mortality represents a real reduction. It may be remarked that no case was treated solely with permanganate injections; subsidiary treatment of the usual type being also followed. The method seemed of special benefit in the case of children and in patients seen at an early stage of the disease.

Whilst I was away on leave the treatment was carried out in a few further cases and also in some of the other hospitals in Port Blair with some success. Since my return from leave I

have treated a further case of left lobar pneumonia in an elderly man of poor physique with success. In this case, in addition to the rectal injections, two intravenous injections of a 1:500 solution of potassium permanganate were given with satisfactory results.

The following are notes on some of the cases treated:—

Case No. 1.—No 44987, Poka, an elderly man reported sick on 6th September, 1926. History of fever for two days with a persistent headache and pain in the chest. Spleen and liver four fingers below costal border. Differential blood count showed 7 per cent. of large mononuclears. Right apical consolidation detected

No... 44987.

Name... Poka.

Date of admission... 6-9-26. Disease... L. Pneumonia.

Hospital... Haddo port blair. Result... Cured.

both in front and behind.

Treatment.—Linseed poultices, Mist. Expect. and Mist. Quinina.

9th September, 1926.—Potassium permanganate solution gr. 2 to one pint of warm water as rectal injections was used as follows:—

Name... Mena.

Date of admission... 16-11-26.

Disease... Pneumonia double.

Date of discharge... 8-12-26.

Result... Cured.

Hospital... Haddo port blair.

4 oz. at 10 a.m.
6 oz. at 2 p.m.
8 oz. at 6 p.m.
10 oz. at 10 p.m.

The expectorant mixture was stopped, and 10 m. of Vinum ipecac was added to the Mist. Quinina.

This routine of treatment was continued up to the 13th September, 1926, and on the 16th September, the lungs were quite clear.

Final notes on this case.—Respiratory relief was obtained early and expectoration soon became free, yellow tinged, and not of the viscid gelatinous kind common to pneumonia sputum, especially in the early stages. The expression, from one of anxiety soon changed to that of comfort; convalescence was rapid.

Case No. 2.—Makbul, aged 7 years. Admitted 10th November, 1926. History of fever, coryza and cough for 7 days. Pain in the chest, fine crepitant râles heard in both lungs scattered about, more in right than in left. Board dullness to percussion on right side. Temperature 103°F. Pulse 120. Respirations 30. Liver and spleen enlarged.

Treatment.—Linseed meal poultice to the chest and back two hourly; potassium permanganate solution gr. 2 to one pint in 10-oz. quantity per rectum four times a day.

R Vin. Ipecac m. 10.

Aqua ad oz. 4.

4 hourly.

On the morning of the 11 November, 1926, the temperature had risen to 105°F. On the 14th morning the temperature had dropped to normal, but there was a rise to 103°F. on the morning of the 15th and the liver was found to be very tender. The child was not distressed in any way. Linseed poultices were discontinued and antiphlogistine used instead, and as there was a history of previous dysentery, 1/8 grain of emetine was given.

16th November, 1926.—The change this morning is wonderful. Breathing deeper and more regular, expression normal, and expectoration free and profuse.

18th November, 1926.—Lungs clearing up wonderfully and the patient practically vomits up a mouthful of expectoration at a time. Temperature has been normal since last evening, Pulse 80. Respirations 22.

Nothing further to record. In all the patient had six emetine injections.

Note.—Cases 1 and 2 came from a village where a mild influenza was active.

Case No. 3.—Female. Mena. Age 35 years. Brought to hospital on 15th November, 1926. Temperature

Case No. 6.—No. 38037, Ganga Singh, aged 38 years, admitted on the 16th November, 1926, with the history that from about 4 a.m. he took bad with fever and a dry cough. Signs of definite consolidation of the base of the left lung were present and the patient had a nasty irritating hiccough. Liver and spleen both

palpable. Blood negative for malarial parasites. Temperature 102.6°F. Pulse 126. Respirations 32.

Name ... Female Basant. Date of admission ... 23-9-26

Hospital ... Haddo. Disease ... L. Pneumonia.

Date of discharge ... 13-10-26. Result ... Cured.

From friends it was definitely ascertained that he was ill for five days before coming to hospital. Post-mortem examination showed massive double pneumonia, and the point of interest from the view of treatment is the fall and control of the temperature.

Case No. 7.—Phree Narain, aged 54 years, admitted on the 29th November, 1926. Fine crepitations audible on the right side. Percussion note dull. Pleuritic rub above base. Temperature 102.6°F. Pulse 128. Respirations 40. Spleen much enlarged, liver palpable. Patient comes from a very malarial area.

Treatment:—Permanganate rectal injections in one pint doses four times daily. Expectant mixture with m. x of digitalis tincture. Linseed meal poultices to chest and back 2 hourly.

30th November, 1926.—Antiphlogistine poultice instead of linseed. Marked consolidation of right lung, middle lobe. Râles and crepitations all over. Pulse 120. Respirations 26.

1st December, 1926.—A markable change. Feels comfortable. Respirations easier. During the night yellow stained expectoration started. Potassium iodide gr. 5 added to each dose of mixture.

4th December, 1926.—Some difficulty in passing urine, and hot packs had to be applied over bladder.

6th December, 1926.—Permanganate treatment stopped. Digitalis reduced, and antiphlogistine discontinued. The points of special interest in this case are that the

17th November, 1926. Temperature has been 100°F. since 4 p.m. on the 16th. Patient had a bad night. Morning temperature 100°F. pulse 140, respirations 48. Scanty yellow stained expectoration has begun. Both lungs are now affected.

18th November, 1926.—Pulse bad, 148. Both lungs consolidated. Marked respiratory difficulty. Hiccough and exhaustion. In spite of all that was done for him, the patient died at 4 p.m.

patient was an elderly man with a constitution undermined by malaria. Although the whole of the right lung was affected there was a remarkable control of the temperature, and once the expectoration started it was profuse, and resolution in the lung took place rapidly.

THE ANTIMONY TEST IN THE EARLY DIAGNOSIS OF KALA-AZAR.

By PASUPATI BHATTACHARYYA, D.T.M.
(Bengal),

Police Hospital, Calcutta.

THE Police Hospital, Calcutta, offers a special opportunity for the study of cases of fever with enlarged spleen, since immediately a member of

the police force reports sick he is sent to hospital and is under observation until he is discharged cured. For this reason one has been able to observe a number of cases which commenced with fever of rather acute type and progressed to fever of chronic type. Those of such cases as do not yield to quinine treatment used to present special difficulty, as one had to wait for a more or less prolonged period before one could diagnose whether the condition present was one of kala-azar or not. At such an early stage of the disease the spleen is not sufficiently enlarged for spleen puncture, whilst facilities for culture of the peripheral blood were not present. Peripheral blood cultures were sent to the Medical College Hospital for report, but they usually became septic. Hence one had to rely on clinical symptoms and on the progressive leucopænia for diagnosis, and in the meantime to institute antimony treatment pending proof that the disease present was kala-azar. The aldehyde test, though valuable, does not become positive before the third month of the disease.

Since the introduction of Major Chopra's antimony test for kala-azar this difficulty has almost been removed. Having studied the technique employed in Major Chopra's laboratory, I have since applied the test to all suspected early cases of kala-azar, and have applied it so far in 51 suspected cases, which are analysed in the table herewith. My experience is that the antimony test, although delicate, is reliable in the early phases of the disease, and therefore of much more value in such cases than the aldehyde test. Of the 51 patients tested, 20 gave a definitely positive antimony reaction, whilst in another 9 cases the reaction was doubtful in character. Two cases gave a positive reading as early as on the 15th day of fever. One case was negative on the 18th day, but positive on the 26th day. One further case was negative on the 22nd day, but was treated with antimony on account of the leucopænia present, and was cured. Of the 20 positive cases, 12 were of less than one month's duration, and had it not been for this test we should have had to wait for one month more before the diagnosis could have been confirmed and treatment instituted. Only one early case of kala-azar in the series failed to give a positive result.

In my experience so far with the test, I have never found a single case of fever—apart from the very chronic cases of such diseases as malaria, tubercle, syphilis—which gave a positive antimony reaction which did not turn out to be kala-azar. In a very early case a negative reaction does not exclude kala-azar, but a positive result appears to always indicate kala-azar. In the case of chronic fever, matters are different. Here an old standing, chronic case of kala-azar always appears to give a positive reaction, but so also do some cases of other diseases, such as chronic pulmonary tuberculosis, chronic malaria, and tertiary syphilis. Major Chopra has recently

advocated diluting the serum with ten times its volume of normal saline in carrying out the test on old-standing and chronic cases, and this method in my experience is certainly useful to exclude non-kala-azar cases.

The aldehyde reaction, if tested by the criteria advocated by Dr. Napier—i.e., a complete gel plus a dead white opacity—we have found to be thoroughly reliable in kala-azar cases of more than three months' standing. We have never found this reaction to be strongly positive in any condition of chronic fever other than kala-azar. In doubtful cases by this method we have tried Major Chopra's method with the diluted serum, and found this to be satisfactory by way of confirmation.

Our present position therefore is this; that all suspicious cases of more than 15 days' duration and less than 3 months' duration are tested by the antimony test. In cases of less than 15 days of fever the antimony test is unreliable. If the antimony test yields positive results, we institute treatment with antimony salts, and so far have never been misled by doing so. Occasionally the antimony test does not become positive until a later stage, and in such cases it is advisable to wait for another week or fortnight, and then to repeat the test. If it is still negative, the probability of kala-azar is negated. Should the disease have lasted for more than three months, both the antimony and aldehyde tests are applied, when both tests usually yield a positive result.

The antimony test, in brief, gives a satisfactory means of diagnosis in just that type of early case where previously one had to wait for a deepening leucopænia, or a sufficient enlargement of the spleen to render spleen puncture possible, or until the expiration of the third month of the disease for the application of the aldehyde test. With the antimony test it is usually possible to confirm the clinical diagnosis and to institute treatment before the 20th day of the disease.

The table included in this article shows the result of application of the antimony test to 51 consecutive cases of fever, where kala-azar had been suspected as the possible diagnosis.

It is realised that it was not possible for me to diagnose these cases by puncture or cultural examinations for L.D. bodies and therefore laboratory workers may doubt my diagnosis. I would like to say, however, that the clinical pictures of the cases, the leucopænia present, and the subsequent reaction to antimony treatment leaves little room for doubt as to the true nature of the disease.

My thanks are due to Major J. C. De, I.M.S., Police Surgeon, Calcutta, who took a keen interest in this enquiry, and without whose sympathy and encouragement it would not have been possible.

Results of the Antimony Test as applied to 51 consecutive cases of fever which might have been due to Kala-azar.

A Mirror of Hospital Practice.

A CASE OF RECOVERY AFTER PERFORATION OF A TYPHOID ULCER.

By J. BA CHOW, L.M.P.,

Sub-assistant Surgeon, Syriam Hospital, Burma.

MARGOON RAI, Hindu male, cowboy, aged 20 years, was brought to the hospital in a taxi from Kyauktan, a distance of about 13 miles on the 21st August, 1927, and admitted at 7 p.m. for the treatment of acute abdominal symptoms of 28 hours' duration.

He was said to have suffered from slight fever for the past ten days. At about 10 p.m. on the 20th August, 1927, he suddenly felt severe general pain in the abdomen, with vomiting and inability to pass stools or flatus. One ounce of castor oil was taken at 10 a.m. on the 21st, but with no results. He was admitted to the Civil Hospital at Kyauktan at 3 p.m. the same afternoon; was then given an enema with no results; and was transferred to Syriam.

Condition on Admission.—Admitted at 7 p.m. very ill, with pinched appearance; hurried, shallow, thoracic breathing, 50 per minute; feeble, frequent, pulse, 130 per minute; temperature, 99.6°F.; tongue coated and dry; abdomen tense and tympanitic, with dullness in the flanks, and tenderness all over, but most marked at a spot two inches below and a little to the right of the

umbilicus. The upper quadrants of the abdomen were noticed to move very slightly, and in an opposite direction to that of the chest, while the lower quadrants remained motionless.

A diagnosis of general peritonitis—probably due to acute appendicitis—was made, and an immediate laparotomy was carried out under spinal anaesthesia; 2 c.c. of stovaine and glucose being given intrathecally. The abdomen was opened by a right lower pararectal incision, when there was a sudden gush of sero-purulent fluid with no faecal odour.

On further exploration, a swelling containing foul smelling pus, mixed with faeces, was found in the right iliac recess. An opening, about 1½ inch in diameter, was detected in the infero-lateral border of the ileum, about 6 inches from ileo-caecal valve, and from this opening faecal matter was escaping. The pus and faeces were gently mopped away and the hole in the intestine sutured.

No other perforation was detected, and the abdominal cavity was sutured with two drainage tubes, one at the lower end of the original incision, and the other in the pelvis. The appendix was normal and was not removed.

After a stormy convalescence of seven weeks, the patient was discharged cured.

Remarks.—The points of interest in this case are the following:—

(1) The fact that the sero-purulent fluid first met with was absolutely odourless, showing that

Nature was attempting to localise the trouble in the right iliac fossa.

(2) The fact that the patient almost certainly owes his life to the use of spinal anaesthesia, instead of chloroform.

(3) His recovery, in spite of the fact that his acute symptoms had been present for 28 hours, and that he had had castor oil and a long motor ride in a jolting taxi over bad roads before admission to hospital.

A FOLKLORE CHARM AGAINST BODILY INJURIES, HYPODERMIC INSERTION OF GOLD NEEDLES.

By B. R. SHENOI,

Sub-Assistant Surgeon, Civil Hospital, Tavoy, Burma.

VARIOUS prophylactic measures against evils are in vogue in different countries. Tattooing the figures of birds and animals on different parts of the body as a charm against *dah* cuts, gunshot wounds, etc., is very common all over Burma. In India, the wearing of beads, rosaries, talismans, tiger's teeth, etc., as charms against evil spirits is well known. The injection of gold needles as a prophylaxis against bodily injuries is to my knowledge rarely practised in any country, except Burma.

N. B. M., a Hindu male, aged 30, a resident of Tavoy, consulted me about two months ago for pain in the flexor aspect of the right forearm. On examination I felt something like a small needle moving under the skin below the bend of the elbow. I suspected some foreign body and on enquiry the patient informed that about six years ago, a *hpongyi* (Buddhist monk) from Siam, injected 18 gold needles in different parts of the body as a charm against bodily injuries. To prove the efficacy of the charm, the patient says that the *hpongyi*, who himself had gold needles in his body, made a cut on his arm which was not followed by any bleeding. The patient further states that he was once assaulted severely on the head by some unknown person at night, and although he was unconscious for a short time, the wound on the head did not bleed and healed by first intention.

It appears, that the *hpongyi* made the patient understand that the charm would act if he took certain precautions (given below), and that he (the *hpongyi*) would take out the needle, whenever the patient experienced any trouble. But unfortunately the whereabouts of the *hpongyi* are not known.

Precautions.—The charm is said to be temporarily ineffective whenever the patient walked underneath a house inhabited by ladies, particularly during their periods of menstruation, pregnancy or delivery.

Operation.—The patient got the gold needles made by a local goldsmith. Each needle is $\frac{3}{4}$ inch long and of the thickness of a fine hypodermic needle. The operation was very simple and quite painless. Neither antiseptics nor

anaesthetics were used during the operation. The patient was made to sit down on a mat, and the operator sat opposite to him. The needles were injected rapidly under the skin one after another in different parts of the body, with a gentle tap of the right index finger after inserting one end into the skin. Arms, forearms and thighs are said to be the favourite sites for injection. The operation was completed within ten minutes. No untoward symptoms followed the operation and the patient says that he has been keeping good health all along, though of late he has been experiencing slight discomfort in the right forearm, below the bend of the elbow.

I advised the patient to be x-rayed and to undergo operation, but he is not willing to do so, though I warned him of the danger attendant on the presence of foreign bodies in the system.

A few days ago I saw the patient again, when he made me feel two needles in the flexor aspect of the right forearm, of which one was slightly bent (this was probably the cause of the pain in the forearm), one on the inner side of the right arm, and one on the flexor aspect of the left forearm. The patient has since been free from pain in the right forearm.

A CASE OF PORRO'S HYSTERECTOMY.

By Mrs. B. E. LEWIS, M.D.,

Female Hospital, Lyallpur.

LACHMI, aged 20, wife of a labourer, was admitted to the Women's Hospital, Lyallpur, on the 28th September, 1927, sent in as promptly as possible by Dr. Jaswant Das of Dijkot, having been treated previously by indigenous *dais*.

The patient had been in labour since 12 noon on the 24th September, the membranes having ruptured about that time. The course of pregnancy up till then had been uneventful. Six years previously the patient had been delivered of a full-time living child, whilst four years previously she had suffered from some vaguely defined febrile illness.

On admission, the patient was found to be poorly nourished, and only 4 ft. 7 in. in height. There was no deformity of the spine or long bones. The temperature was 102°F., pulse 120, the tongue furred. The abdomen was extremely distended and continuously painful, and very tender. No evidence of rhythmic contractions was found. The head was not engaged in the pelvis and the foetal heart sounds were not heard. There was a foul-smelling discharge; the os admitted two fingers; and the membranes were ruptured. The pelvic measurements—(taken later during convalescence)—were as follows:—

Interspinous—7 $\frac{5}{8}$ th inches.

Intercristal—8 $\frac{3}{4}$ th inches.

Oblique conjugate—3 $\frac{1}{8}$ th inches.

The transverse diameter was so contracted that it admitted little more than one finger. An x-ray plate—(also taken during convalescence)—showed the triradiate deformity of the brim characteristic of osteomalacia.

Immediate operation was carried out by the Civil Surgeon, Lieut.-Col. R. T. Wells, M.D., F.R.C.S.E., I.M.S., under chloroform anæsthesia.

The gravid uterus was delivered completely outside the abdomen through a long incision, and packed off with swabs, the edges of the wound behind it being temporarily held together with forceps. When the uterus was incised it simply split up. The placenta was first encountered, and separated without bleeding. A full-time child was then removed. Both ovum and decidua were green and foul-smelling.

A rubber tourniquet was then tied firmly round the cervix, which was transfixed distally by two strong knitting pins. The tubo-ovarian arteries were ligatured separately, and the uterus was amputated distally to the transfixation pins. The stump was fixed exterior to the surface in the lower end of the wound, the remainder of which was sutured in layers as usual.

After operation the patient's temperature ranged between 100 and 102°F. for eleven days. The gangrenous stump became highly offensive. The patient, however, expressed complete relief on coming round after the anæsthetic, and convalescence was uninterrupted. The stump, with its tourniquet, separated on the 11th October, whilst the rest of the wound healed by first intention.

The lower end of the wound presented a deep granulating crater, which healed slowly, and the patient was discharged cured on the 6th November, when her general health and state of nutrition were excellent. She made the pathetic request that she might be admitted to the same hospital for her next confinement.

Had this patient come under observation during her pregnancy, the ideal treatment would have been Cæsarean section, with sub-total hysterectomy, at full term. Under the desperate circumstances present at the time of her admission to hospital, however, it does not seem possible that any operation other than Porro's hysterectomy would have saved her life.

This operation is generally considered as of only historic interest, but in such countries as India, where osteomalacia may give rise to extreme degrees of pelvic contraction, and where antenatal care is unknown, it may evidently still find application.

My thanks are due to Colonel Wells, I.M.S., Civil Surgeon of Lyallpur, for permission to publish these notes.

DEEP INFILTRATION ANÆSTHESIA OF THE ORBIT IN EYE OPERATIONS.

By R. A. KALLE, M.B., B.S.,
Sirsi, Kanara District.

I HAVE read with great interest the article contributed by Major J. N. Duggan, D.O. (Oxon.), of Bombay, describing in detail the method of deep infiltration anæsthesia of the orbit. Since then I had occasion to use this

form of anæsthesia in 11 cataract operations and in 2 cases of sclero-corneal trephining operations for sub-acute glaucoma. Though this is not in itself a big record to go upon, yet the uniform success which I got in these cases encourages me to write this note. The object of this method is to block the motor and sensory nerves coming from the ciliary ganglion. If the injection is well made, it is surprising how complete the anæsthesia is, so much so that I am inclined to use this as a routine method. Given a sharp pointed, fine needle $4\frac{1}{2}$ cms. long, the injection of the novocaine solution itself is quite painless. Even in enucleation of the eyeball Major Duggan writes to me to say that if the strength of the novocaine is increased to a 4 per cent. solution, there is no pain, even while cutting the optic nerve, provided the injection is well made.

As the amount of eye work that I get here is not great, I prefer to use novocaine and suprarenalin solution 2 per cent. supplied ready-made in ampoules. I have found this solution quite satisfactory.

For those in the mofussil who do not usually work under ideal conditions and who have frequently to depend upon unskilled assistants this method of anæsthesia is particularly useful. When once the injection is made the interval of 40 minutes (the usual time to be allowed between the injection and operation) can be advantageously utilised in looking after the sterilisation of instruments, etc.

I should be pleased to see recorded in your journal the experience of those who have used this method. When authorities like Major Duggan recommend this method, it would be a presumption on my part to do so, yet to those who take an interest in this field of surgery I would recommend a close study of his article.

This method was proposed by Duverger of Strassbourg in 1918 (Ball), but the credit of bringing it to the notice of ophthalmic surgeons in India belongs to Drs. Green and Icove of America and to Major Duggan who has brought it to the notice of the readers of your journal.

SODIUM CACODYLATE IN THE TREATMENT OF BOILS.

By BIDHUBHUSAN GHOSH, L.M.F.,
Shahazadpur, Pabna District.

LAST year, though the summer and rainy season were not very hot, yet summer boils were a constant source of trouble to many children and young adults in this part of Pabna District. Children between the ages of 3 and 7 were the patients most affected, the head and forehead being the favourite sites, though the extremities were not exempted.

In March 1927, I had ten cases, most of them children of poor stock. I tried the usual routine treatment, and tinct. ferri perchlor., digitalis, quinine, citric acid, potassium chlorate, belladonna, etc. Two of the patients could afford to

buy vaccine, and these two cases promptly cleared up. In the others fresh crops of boils continued to appear, despite the most careful aseptic technique and treatment.

At the time I had under treatment a patient suffering from chronic asthma, who also developed boils. I treated him by hypodermic injections of sodium cacodylate for the asthma, and to my surprise all the boils cleared up after the first two injections. I then began to treat all my cases of furunculosis by hypodermic injections of sodium cacodylate, given on alternate days, and found this method of treatment invaluable. Not more than four injections are necessary as a rule before all the boils clear up, and no further ones appear.

Furunculosis is so common a complaint that its treatment is rather neglected, but in sodium cacodylate we appear to have an almost specific cure for the complaint.

A CASE OF MELANOTIC CARCINOMA.

By B. R. SHENOI, L.M.P.,
Civil Hospital, Tavoy, Burma.

CASES of melanotic carcinoma which rapidly end fatally are rare. The case cited below may, therefore, be of some interest to the readers of the *Indian Medical Gazette*.

M.C.M., aged 44, a prisoner from the local jail was admitted to the Civil Hospital, Tavoy, on the 22nd April, 1927.

Previous History.—The patient was the headman of a village in the Tavoy District and was in good circumstances before conviction. He was sentenced to 3 years and 6 months' rigorous imprisonment and was admitted into the District Jail, Tavoy, on the 20th August, 1924, in good health, and he continued to keep good health in the jail for two years thereafter. On the 20th December 1926 he was admitted into the Jail Hospital, Tavoy, for the treatment of a left femoral bubo, which was operated upon the next day under chloroform and the diseased glands were removed. The patient made an uneventful recovery and was discharged on the 30th December, 1926. About two months later the patient struck his left foot accidentally against a stone, which resulted in an ulcer on the sole of the foot for which he was treated as an out-door patient. The ulcer, however, got worse and looked like a chronic fungating growth at the time of admission into the jail hospital on the 9th April, 1927. The left femoral glands were found to be enlarged, painful and tender. Enlargement of the left iliac glands followed in the course of a day. The patient ran a hectic temperature. On the 11th April, 1927 fluctuation was elicited in the femoral region. On the 12th April, 1927, the bubo was incised under chloroform, pus let out and the diseased glands removed. The patient was apparently well after the operation and the temperature came down to normal. On the 17th April, 1927, however, the

evening temperature suddenly rose to 105°F., and was followed in a few hours by distention of the abdomen, retention of urine, and motor paralysis of the lower extremities with retention of sensory function. Bedsores formed three days later, followed by incontinence of faeces. He was transferred to the Civil Hospital, Tavoy, on the 22nd April, 1927, for further treatment, as proper facilities for nursing do not exist in the Jail Hospital.

His condition, however, got worse day by day in spite of careful nursing and treatment, and he died on the 28th April, 1927.

On post-mortem examination the following pathological changes were noticed:—

1. Destruction of the 2nd rib on the right side.
2. Destruction of the body of the 2nd dorsal vertebra.
3. Nodular deposits of various sizes in both lungs.

The viscera were sent for examination to the Director, Pasteur Institute of Burma, Rangoon, for histological investigation, who reported the condition to be melanotic carcinoma with secondary deposits.

Peculiarities of the Case.—(1) The trivial injury which, if one can say so, acted as an exciting cause for the malignant growth on the sole of the foot.

(2) The sudden onset of malignant disease after receipt of the injury.

(3) The fatal termination of the case within an unusually short time after the appearance of the disease.

(4) The absence of local signs and symptoms in spite of extensive destruction of the 2nd rib on the right side.

(5) The uncommon and rapid destruction of the 2nd dorsal vertebra, due to secondary deposits from the original growth on the sole of foot, followed by motor paralysis of the lower extremities with retention of sensory function.

In conclusion I desire to express my grateful thanks to Dr. B. T. Chain, B.A., M.B., Ch.B. (Edin.), Civil Surgeon and Superintendent and Medical Officer of the District Jail, Tavoy, for the previous history of the case and for granting me permission to publish these notes.

AN INTERESTING CASE OF THE LIPOMA OF THE CHEEK.

By CAPTAIN B. P. DARUVALA, M.C.P. & S.
(Deolali).

A MALE aged 30 years was passing by my dispensary, when I noticed a swelling on his right cheek, and being interested in doing surgical work I called him and asked him as to what the matter was with his cheek. He at once opened his mouth and caused a pedunculated tumour to project from his mouth, as shown in Fig. 2.

I call this case interesting, for the reason that usually fatty tumours bulge outwards and have

a tendency to grow externally, whereas this tumour pointed inwards in the direction of the buccal cavity contrary to the usual observation, and it presented an appearance of a polypus

Fig. 1.

protruding from the os uteri. I have sent two pictures of this patient, one to show him as he appeared to the observer from a distance (Fig. 1),

Fig. 2.

and the other to show to the reader the picture of the tumour as it appeared on closer inspection (Fig. 2).

The patient having agreed to operation, it was carried out in the following manner. The tumour was made to protrude through the mouth, as in Fig. 2. A clamp-forceps was applied to the pedicle and the mucous membrane was incised in front of the forceps and the tumour separated by a few touches of the knife. There was no bleeding to speak of. Lastly, the wound was sutured, and healed in due course of time.

A NOTE ON THE INTRAVENOUS ADMINISTRATION OF SODIUM BICARBONATE IN BLACKWATER FEVER.

By EDMUND BURKE, L.R.C.P., L.R.C.S.
(Edin.),

*Medical Officer, Bishnauth Medical Association
(East Boroï Section), Assam.*

H. M. HANSHELL of London records an interesting case of blackwater fever in a European male patient which he treated by intravenous infusions of sodium bicarbonate alone with remarkable results. This was in September 1925.

A month later (October 1925), Baker and Dodds published the results of their experiments with regard to intra-renal obstruction, such as was observed in two patients who died from renal insufficiency following transfusion of incompatible blood.

Referring, in part, to Hanschell's more extensive paper, perhaps the following brief resumé of the results of Baker and Dodds' work may here be mentioned before describing a very interesting case. Their conclusions, briefly put, were that hæmoglobin introduced into the circulation is excreted by the kidney. Thus:—

- (1) If the urine reaction be above pH 6, the hæmoglobin will all be excreted as oxy-hæmoglobin; the urine red, and no ill effects result.
- (2) If the urine reaction be below pH 6, and there be a sufficient concentration (1 per cent) of Na Cl, brown pigment will be precipitated in the tubules.

These workers show that in cases of hæmoglobinuria the factors leading to precipitation of brown pigment in the uriniferous tubules are acidity and salt concentration of the urine, and that the treatment should be one that will prevent undue hæmoglobin precipitation in the tubules such as occurs in blackwater fever.

They indicate that, as distinctly acid urine with a reaction below pH 6 is the chief and most favourable factor in producing this so often fatal blockage of the kidney tubules in blackwater fever, an alkaline state of the blood is essential for the prevention of such an occurrence in the course of the malady. The administration of alkaline diuretics or transfusions would, therefore, seem most appropriate if treatment is to be effective.

Such was Hanschell's method, and it was only after the work of Baker and Dodds had been published that he decided to record his single case thus successfully treated.

The writer recently had the good fortune to attend a very severe case of blackwater fever within four hours of the onset of hæmoglobinuria and it was decided that sodium bicarbonate should be administered intravenously. The result of the treatment being remarkably successful, the writer ventures now to record the case in order to confirm one well-known observer's findings, and with the hope that it may prove of interest to others.

Case.—Babu A. Kumar Das, Hindoo, aged 27 years, of Borma Jan Tea Estate, Assam. Had had fever on and off for some years though never severe. Had never taken "prophylactic" quinine. Always fairly healthy but for the mild bouts of fever.

October 8th, 1927.—Patient developed fever (101–103°F.) more severely than any previous attack. Had lumbar pain and severe bilious vomiting.

October 9th, 1927.—At 10 a.m. he passed about 3½ ozs. of dark brown urine. At 11 a.m. less urine passed, the colour now being absolutely black. The writer was then summoned and reached the patient at 3 p.m. No more urine had been passed since 11 a.m.

Clinical Picture.—Patient had deep jaundice, an anxious facies, severe headache, profuse and frequent bilious vomiting, shallow respiration, a rapid, weak pulse of 130. Heart sounds feeble and hæmic murmurs present. Temperature 104.6°F.

Bad bilious diarrhoea present, 7 or 8 motions having been passed between 9 a.m. and 3 p.m.

No treatment had been possible by the mouth owing to the severe vomiting.

The alkaline treatment described by Hanschell was adopted, and accordingly 150 grains of sodium bicarbonate were dissolved in 20 fluid ounces of distilled water, the whole being then sterilized by boiling for 5 minutes.

No infusion apparatus being quickly available an ordinary 20 c.c. all-glass syringe was used and the drug administered intravenously 20 c.c. at a time.

This laborious and somewhat precarious procedure was continued until 17½ ounces of the solution had been administered when the patient began to react so severely that the last 2½ ounces were withheld.

A hypodermic injection of strychnine and digitalis was given and the patient gradually recovered. No other drug was used after this.

At 5-10 p.m. (1 hour after the infusion) 5 ozs. of urine were passed naturally—the first since 11 a.m. and the colour was now dark brown with much deposit. Vomiting still continued, nothing being retained if given by the mouth.

15 ozs. of warm normal saline were then given per rectum and retained.

By 6 p.m. the pulse was noticeably improved. Patient's general state better. Bilious diarrhoea had stopped. Vomiting now showed signs of abating. 8-55 p.m. 8 ounces lighter coloured urine passed.

Diuresis seemed immediately and definitely established, and by midnight the urine was of a bright port-wine tint and clear.

That night the patient slept for 4 hours. Eighteen hours after the sodium bicarbonate infusion the urine was absolutely normal in colour and quantity and there were no deposits of any kind.

One or two slight rises of temperature occurred for the next two days, the urine then becoming a little darker and cloudy. After that as much as 1600 to 1800 c.c. of urine were passed in 24 hours though albumen was present in fairly heavy deposit now.

Convalescence progressed rapidly, though the patient nearly collapsed on the eighth day while struggling during the administration of an enema for obstinate constipation following the former bilious diarrhoea.

On the twenty-fourth day the patient was considered cured, and after a brief treatment for his weakness and anæmia proceeded on a month's holiday to fully recuperate.

Interesting features are:—

(1) The patient was never in the habit of taking "prophylactic" quinine. His blackwater fever therefore was not connected with abuse of this drug.

(2) No other drug was used throughout the illness except the sodium bicarbonate.

Water, of course, was pushed after the vomiting ceased.

(3) The marked diuresis and rapid return to normal of the urine produced by the comparatively small amount of sodium bicarbonate given—17½ ozs. (Hanschell gave his case two infusions of one pint each.)

(4) The sodium bicarbonate undoubtedly promoted rapid and definite diuresis with alkalinity, thus preventing suppression from renal obstruction due to precipitated hæmoglobin in the kidney tubules.

In closing I must acknowledge my indebtedness to my patient for proving so interesting a case, for submitting to the experimental treatment, and for his permission to publish his name.

My thanks are due also to Babu N. Lallā, my assistant, for his well kept case-notes, for carefully measuring the numerous samples of urine, and for his careful nursing of the patient.

Note:—Since writing this report I have heard the regrettable news that my patient and his wife both died of cholera on December 17th, while on holiday.

A CASE OF MELANCHOLIC ATONIA OR PSYCHOCOMA.

By A. BAYLEY DE CASTRO,

LIEUT., I.M.D.,

Junior Medical Officer, Haddo, Port Blair, Andamans.

IN the *Indian Medical Gazette* for August 1920, a case of psychocoma is recorded by Major St. John Moses, I.M.S., from the Berhampore asylum; and although Ewens says in reference to this phase of insanity that "it is a condition not at all infrequent in Indian asylums," I have only had one admission into the small asylum under my charge in Port Blair during the past seven years. Overbeck-Wright gives a very accurate though long definition of this disease in which he includes the three stages of katatonia.

In this so-called stuporous type it should be remembered that there is no true stupor—but that this name is applied because of the immobility and mutism of the patient.

Stoddard considers katatonic stupor to be the most characteristic variety of dementia præcox, and this raises the point as to whether such cases should not be diagnosed dementia præcox straight away, instead of calling them by the fanciful names of melancholic stupor, atonia, or psychocoma. Katatonic depression was first described by Kahlbaum in 1872. Such patients go through a prodromal stage, and my patient no doubt was going through his prodromata when caught and sent to me.

The history of the case and symptoms are as follows: No. 44922, a young well developed Moplah of about 27 years of age, was found wandering about in the jungle on the 11th December, 1926. He had been absent from his station for three days. He had a very vacant expression, took no interest in his surroundings, answered questions with difficulty and then only after repeated questions.

Reflexes normal, and no Argyll-Robertson pupil. Spleen $1\frac{1}{2}$ " below the left costal margin. Liver normal, and *Plasmodium falciparum* rings in the blood.

Differential blood count showed:—

- 47% Polymorphonuclears.
- 48% Lymphocytes.
- 2% Large Mononuclears.
- 3% Eosinophiles.

While a total leucocyte count gave 13,750. The hæmoglobin value was 80 per cent. A marked leucocytosis is one of the features of the depressed variety of katatonia or psychocoma.

The patient was of course put on to active antimalarial treatment with the hope that all his trouble was due to this: and certainly as far as the malaria was concerned rapid and permanent results followed, but not so with the mental state which by now (5-1-27) had advanced further. The notes for that date state that "he will not answer questions, is not keen on his food—remains in his cell in queer postures (sits at times bent over to the right side, or while in a squatting

posture throws his head either forwards or backwards or else lies on his left side curled up). He does not like being interfered with." He always kept his eyes tightly shut, and showed marked resistance when they were forcibly opened. He always had to be coaxed to eat, but on the 9-1-27 he refused food altogether, and forcible feeding had to be resorted to: a few days after this he started to take milk and congee but refused all solid food.

The face muscles remained fixed, the eyes tightly closed and from now (20-1-27) he was always found lying on the left side with his legs fixed; (thighs flexed on abdomen, lower leg from the knee down flexed on back of thigh) and arms crossed over the chest. A slight mucous secretion was found exuding from the external canthus of the eyes.

Constipation was very marked, all reflexes remained normal, and no trophic lesions of the skin developed all through the period of his illness. On the 14-2-27 patient opened his eyes and spoke. He asked for a drink of water, a few minutes later he once again laid down, coiled himself up, shut his eyes and lapsed into his former state. 20-4-27—Lies in an inert manner all day and night in one corner of his cell, the body being kept in a state of flexion.

This condition and state of affairs lasted till the 15-7-27, when a very sudden and wonderful change occurred. The patient now suddenly woke up. From now to the date of his transfer to India in October 1927, there is nothing special to record. His intelligence did not return all at once, but gradually, and finally before he left the asylum he had become fat.

Ewens states that "obstinate resistance with retention of memory and consciousness are marked and indeed essential features." This was most strikingly displayed in my case.

SPECIAL REPORT.

THE SEVENTH CONGRESS OF THE FAR EASTERN ASSOCIATION OF TROPICAL MEDICINE, held at Calcutta, from December 5th to 10th, 1927*

No more brilliant or more important medical congress has ever been held in India than the Seventh

* In constructing this special report, the reviewer would like to acknowledge his indebtedness to several different sources; to the columns of the *Calcutta Statesman* and *Englishman*, from which he has borrowed freely, especially with regard to the opening and closing sessions of the Congress; to the different individual 'rapporteurs' of different sections of the Congress, who have supplied him with notes or complete reports of their sectional sessions; and to others who have contributed notes, corrected sections of the MS, or supplied information.

Biennial Congress of the Far Eastern Association of Tropical Medicine, which was held in Calcutta from December 5th to 10th, 1927. The Congress was especially remarkable in two respects; the large number of distinguished foreign delegates, and guests of the Government of India, who attended it, and the tributes which were paid by our visitors overseas to the medical research work which is going in India at present. There was no lack of the latter; indeed, the general impression which one gathered from the remarks by our guests was that they had previously had no conception of the extent and the degree of organisation of medical research work in India. This is perhaps not surprising; the Indian Research Fund Association was organised by the late Sir Pardey Lukis in 1906-07, and is a much older body than the National Medical Research Council of Great Britain, which was organised in response to the necessities of the Great War. In organisation and breadth of programme the Indian organisation bears favourable comparison with the much wealthier organisation in Great Britain. Perhaps one of the most important results of the Congress will be to broadcast and make known the work which is being done in India, and to establish closer touch with workers in other countries in Asia.

The official foreign delegates numbered some 95. They included representatives of the Medical Research Council of Great Britain (Sir Walter Fletcher); the League of Nations (Professor Theodore Madsen of Copenhagen); the British Ministry of Health (Lt.-Col. S. P. James, I.M.S., ret'd.); and the Rockefeller Foundation (Dr. Victor G. Heiser); together with official representatives of some 18 Asiatic countries outside India, and delegates from Australia and Egypt.

It is difficult in retrospect to give any connected narrative of the Congress, for its activities were very widespread. No less than six sessions met daily, and the number of papers presented exceeded 240. It is nevertheless perhaps possible to attempt at this early stage to give, as it were, a bird's-eye view of the Congress.

OPENING CEREMONY.

Approximately 1,000 delegates and members were present at the opening ceremony which was held in the Senate House of the Calcutta University at 10 a.m. on Monday, December 5th. The proceedings were opened by His Excellency the Governor of Bengal (Sir Stanley Jackson), and we take the following abstract of his speech from the *Statesman* of the following day;

In opening the proceedings His Excellency the Governor said: "Gentlemen, I deem it a great privilege to have the honour of opening this Congress to-day. His Excellency the Viceroy has asked me to convey a message to you which I will now read:—

"It is with great pleasure and with a keen sense of the importance of the occasion that I welcome your Association to-day. India early recognized the possibilities of the movement which started, I understand, by the enterprise of a small group of earnest workers in Manila in 1908, and has progressed until now it embraces nearly all countries of the Far East, and is generally recognized as the most representative and authoritative organization dealing with the public health and diseases of warm climates. We are, therefore, highly gratified to have the opportunity of welcoming its members to India, where there are still such great opportunities for those interested in medical research. Indian representatives on your Association have been hospitably entertained in the past in Manila, Hongkong, Saigon, Java, Singapore, and Tokio. I trust that our guests may carry away as pleasant recollections of this Congress as our own delegates preserve of previous gatherings elsewhere. I wish your Congress all success. I feel sure that the free interchange of thought and the opportunities for meeting, under pleasant social conditions, workers of different nationalities and varying experience will have a real value for those who are gathered here to-day."

Continuing, the Governor remarked: "This is the Seventh Congress of the Far Eastern Association of Tropical Medicine, though it is the first to be held in Calcutta. The history of medicine in India begins with the Vedas, which are believed to date back to 1500 B.C. but the best known names in connection with Indian medicine are Sushruta and Charaka, who flourished about five or six hundred years before the beginning of the Christian era. Their writings are, I understand, still revered by many practitioners of medicine in India, and all of us can unite in paying homage to these great men of old who lived and worked before the time of Hippocrates.

"The modern history of medicine in Calcutta contains some names of special interest to workers on tropical diseases. The names of Timothy Lewis and David Cunningham will be familiar to many of you. Their work was done at a time when interest in medical research was low, and so their discoveries have not received the recognition which they deserve. You are all familiar with the epoch-making discovery which was made by Major Ronald Ross, about thirty years ago. You will be interested to see here in Calcutta the little laboratory in which he toiled and wrested from Nature her jealously guarded secret of the transmission of malaria. It is a matter of great regret that Sir Ronald, now full of years and honours, is prevented by ill-health from being with us to-day. You are also familiar with the work of Sir Leonard Rogers, who worked for many years in the Medical College, where many of your meetings will be held.

"Sir Leonard was not merely a research worker, but he was responsible for the erection of the new School of Tropical Medicine and Hygiene in which a small band of workers are engaged in pursuing the researches which were, and still are, the obsession of Sir Leonard's life. The work done by Ross and Rogers will always be proudly remembered in India, and this School in Calcutta is a fitting and worthy monument of their labours, skill and perseverance. There are men who are now engaged in medical research in Calcutta and doing splendid work. You will see them for yourselves and I am sure that they will greatly appreciate the opportunity of exchanging ideas with fellow workers from Japan, China, the Dutch East Indies, the Philippines, Indo-China, the Federated Malay States and the other countries of the Far East, as well as workers from America and Europe. Your presence here is most gratifying, and for two reasons, one is that we may show you what is being done here; and what is perhaps more important, that we may learn from you and obtain suggestions for the improvement of our work.

"Among our welcome guests are men whose names stand out pre-eminent in the domain of medical discovery. Drawn from all nations of the world, they possess a wide and varied experience of the ravages of tropical diseases—many of them have fought all their professional lives with these enemies of humanity and in many cases have defeated and exterminated them. During your visit you will discover and appreciate the vastness and complexity of the problems which confront our workers in India, and if you make your survey of India in a sympathetic spirit, you will probably realize the serious efforts which are being made in Bengal and all over India for the control of disease.

"From the early days of British rule in India the importance of public health was realized, but the policy of Government was based on the view that it was necessary first of all to educate the people and to secure their goodwill towards public health measures. For this reason attention was first concentrated chiefly on medical relief. This may not have been the quickest way but it was probably the surest and safest, and that the policy has justified itself is proved by a steadily growing demand not merely for doctors, but also for health officers. Prevention is better than cure, but we cannot force preventive measures on unwilling people any more than you can compel a horse to drink merely by bringing him to the water.

"There are some hopeful signs in Bengal. I am informed that thousands of people are coming for intravenous injections for the treatment of kala-azar which is one of our special scourges. Inoculation against cholera is readily accepted by people who a few years ago would have resisted to the death. People with early leprosy are coming forward in numbers for treatment, and generally there is a gratifying increase of the receptiveness of the people for modern methods of treatment and prevention of disease. Another hopeful sign of the times is the rapid rise of voluntary co-operative societies for the control of malaria and kala-azar; the success of these is chiefly due to the efforts of a former assistant of Sir Leonard Rogers—Rai Bahadur Dr. Gopal Chandra Chatterjee.

"The awakening of a spirit of self-help is a great advance; it greatly facilitates the work of Government agencies and it is likely that Dr. Bentley will be able to show you how rapidly the attitude of the people is changing. Apathy and indifference are disappearing and in many places there is an embarrassing demand for preventive measures, especially against cholera. More inoculations against this disease have been carried out in the past few months than in all the years since the introduction of anti-cholera inoculation. If we lay stress on the hopeful signs, you must not imagine that we minimize the difficulties which still lie ahead; the obstacles to advance have not yet been swept away, but it is important that they are beginning to yield and it is likely that we are approaching a period of interest in public health which will require even more tactful handling than the prolonged apathy of former generations.

"Research work appears to have outstripped the practical application of the results of research, but we cannot afford to call a halt in research. Every new important discovery has a great value in promoting the efficiency and economy of public health measures. The recent discoveries in connection with the treatment of kala-azar have made it possible to organize a campaign against that dreadful disease, whereas a few years ago we have had to look on while the people died miserably. The discoveries which remain to be made in the future will doubtless be of great value in simplifying the problems of preventive medicine, and it is for this reason that the Congress of Medical Research Workers have been welcome guests in every country which they visited.

"Such a Congress as this should be welcomed to Bengal as a relieving army to the besieged. We in this Presidency are unfortunately the victims of several virulent scourges such as cholera, which at the moment it very rife, malaria and kala-azar, and we are hopefully looking to the results of your deliberations to help us along the road towards some relief.

"I beg to offer this Congress a hearty welcome to this city and to Bengal and to express the hope that their stay here may prove enjoyable and that your memories, when you leave, will be in all respects satisfactory and agreeable."

The President of the Congress, Major-General T. H. Symons, C.S.I., O.B.E., K.H.S., I.M.S., Director-General, Indian Medical Service, then delivered his opening address. In extending a welcome to the delegates he said:—

"This is the first time the F. E. A. T. M. has honoured India in making it its centre of activities; I can only hope that it will not be the last. I can assure those who have come from afar that India is prepared to give you of its best and we hope most sincerely that you will go away with very pleasant recollections of your visit. As President of this great assembly I am sure you would like me to take this opportunity of expressing our thanks to His Excellency Lord Irwin, the Viceroy of this great country, for his message of welcome, sympathy and encouragement which His Excellency Sir Stanley Jackson has just read out to us. It is most fortunate that we should have at the head of the administration of this

country a man of such sterling qualities, immense capabilities and sympathetic tendencies towards our work, and we regret most sincerely that His Excellency is not able to be here to-day.

"His Excellency Sir Stanley Jackson, the Governor of this Presidency, most kindly consented to open the conference and it is my pleasurable duty, Sir, to thank you on behalf of all present, not only for coming here to-day and opening the conference at no inconsiderable inconvenience to yourself, but also for taking such an interest in the proceedings, and extending your hospitality to members at a Garden Party and a Reception at Government House.

"I would like also to thank this City of Calcutta for the welcome which it has extended to the members of the Congress."

Describing the purpose of the Congress the President continued: "These conferences—and the same applies to all medical conferences the world over—are held mainly for one purpose, the increase of our knowledge of disease. Race, religion, colour and sect form no barriers where scientific medicine is concerned. If we as a profession can so combat disease that big epidemics, infantile diseases, and preventable scourges like tuberculosis, cholera, syphilis, leprosy, etc., become either diseases of the past or continue to exist only to a greatly reduced extent, surely we shall have done a great thing for future generations.

"It is an important feature of such congresses as this, that they emphasize to our profession and to the public the great importance of measures against disease in tropical countries, and bring home to the government of such countries a fuller realization that the organization of adequate public health administration is one of the greatest of their many responsibilities.

"Whenever I think of the work done, and often under the most adverse conditions, by the members of medical scientific associations, it always leaves me with two very satisfactory feelings. The first is the amount of work which is being carried on whereby the secrets of Nature are being investigated and turned to the advantage of mankind generally; the second that I have the honour of being a member of that profession which, I have no hesitation in saying, is second to none. Instances are many where the worker has gone out into the garden of pestilence never to return. The death in 1924 of Major Cragg, I.M.S., from typhus fever which he was investigating was a serious loss to our Research Department, while the recent tragic death of Adrian Stokes is so fresh in your memories that it requires no words of mine to remind you of it. He met his death whilst putting the finishing touches to an investigation of one of the most virulent and fatal diseases known to man."

Referring to the problems that exist in connection with epidemic diseases in India, General Symons said: "You will realize that India is not a country, in the ordinary sense of the word, but is rather a sub-continent; it is in fact equal in area and more than equal in population to Europe minus Russia. If you grasp this fact you will at once see how difficult is the question of tackling all the interesting and important questions which arise in connection with epidemic diseases. Another point—India is a country of many races, religions and languages. You may say there are many languages, religions, etc., even in Europe, but I can assure you that the north and south inhabitants of Europe are by no means so far apart as the north and south population of this country. If I were asked to point out similarities between the Pathan of N. W. India and the Tamil in Tuticorin I would find it difficult to do so.

"During the course of your tours I think it is more than probable that you may at times jump to the conclusion that perhaps more could have been done along the lines of public health and sanitation. I assure you that there is no body more alive to this fact than the medical profession in India. In this connection special difficulties exist. Practically all medical relief in this country is State aided and the

State or rather multiples of States are—like most other States in the world—in a chronic condition of trying to balance their budgets. Help from private individuals, those who could afford to come forward handsomely, is not so frequent as we would wish. Moreover when we are presented with a hospital, very rarely is it endowed, so that not infrequently its utility is seriously interfered with for want of funds.

"Then we have the psychology of the population to consider. The average individual either through ignorance or apathy—more frequently the two combined—does not want any improvement in the standard of living. He is quite content to carry on in the same groove as his ancestors did before him, and you may take it from me, that it takes a mighty big jolt to shift him out of that rut. There are some who speak disparagingly of the work done by the medical profession in India. They either know nothing concerning the subject, or do not realize what the profession is up against. There may be instances where individuals have not perhaps given of their best; that applies to every walk in life; but, speaking as the head of the medical profession in this country, I can assure you that we are quite prepared that our work should be judged by the best of all judges and critics—time, feeling confident that the mound of knowledge which we have helped to erect, the work which has been carried out, on occasions even with loss of life, will stand as a monument to our activities and testify to what was done to try and improve the conditions.

"You will expect me to give some idea of what has been done in this country in tackling the subject of disease. You are already aware that India is the home of many epidemic diseases—diseases which have a bearing of a world-wide nature. I have only to mention cholera and plague to create many thoughts and remind you of many incidents in connection with these two scourges. Then again India is rife with diseases like enteric fever, malaria, venereal, kala-azar, small-pox and the like. A lot has been done and is being done to combat these diseases, and when I tell you that only last February, March and April there occurred a pilgrimage at Hardwar when eight millions visited the shrine from all parts of India during a period of 90 days and only 58 cases of cholera occurred, you will at once realize how thorough must have been the arrangements, because those of you who know anything about these pilgrimages know that the material is always there and only requires the spark to bring about an enormous outbreak. I visited the town just before the most important day and was greatly impressed by the prophylactic measures which had been put into practice. Protection of such a number against cholera by inoculation was impossible, even if the pilgrims had been willing to submit to it. I have mentioned the above incident, because it demonstrates concretely the kind of problems which the Public Health Department is called upon to face in India and, incidentally, the very thorough manner in which it was tackled.

"Plague is another disease which causes us a great amount of anxiety. It was first introduced into Bombay in 1896, and, finding a suitable soil, and environments which were pre-eminently favourable for its rapid dissemination, it spread rapidly throughout the Bombay Presidency. Such a disease called for drastic measures and at the time the only one which proved efficacious was immediate and complete evacuation of the infected area. Thanks to the original work done in the Research Institute at Bombay a vaccine was discovered which has proved to be most effective as a prophylactic. Nowadays immense quantities of this prophylactic are being used annually. In the province of the Punjab alone seven lakhs (7,00,000) of doses were given during 1926. This will give you some idea of the work. Such of you as go on the tour will be able to see the large scale production of this vaccine at the Haffkine Institute, Bombay.

"Malaria yearly claims many victims; in fact far too many. The prevention of this disease in a country

like India is a matter on which those of you who are interested will be able to take part in the discussions of the scientific sessions."

In conclusion the President said: "We are carrying on the good work in this land of India. We are aware that the field is large—I might say immense. In the face of great difficulties which are ever present we mean and are trying to place this sub-continent in its proper place in the world of scientific medicine and we hope when we leave that those who follow will see that the position is maintained."

After the opening session, the Congress divided itself into six sections which held simultaneous meetings morning and afternoon from Monday until Saturday. The subjects dealt with were so numerous, and the discussions covered so much ground that it is impossible to deal with them comprehensively. We may choose, however, certain of the more important subjects dealt with individually for report.

MALARIA.

Malaria Control. Perhaps no section of the Congress was of more vivid interest than the discussion on malaria control, which occupied two days in the crowded lecture theatre of the Medical College. There were present some of the most distinguished malariologists in the world, and the proceedings were listened to by a very large audience. Professor J. W. W. Stephens represented the Liverpool School of Tropical Medicine; Sir Malcolm Watson the Federated Malay States; Lieut.-Col. S. P. James, I.M.S., (retd.), the British Ministry of Health; Dr. Hoops and Dr. Scharff came from Singapore; whilst India was represented by Colonel S. R. Christophers, F.R.S., I.M.S., Major J. A. Sinton, V.C., I.M.S. and Mr. R. Senior-White; and Bengal by Dr. Bentley, Dr. C. Strickland, and Mr. M. O. T. Iyengar. These names alone will give some indication of the importance and impressiveness of the occasion.

The proceedings opened with a paper by Sir Malcolm Watson in which he outlined the present and future of malaria control in the F. M. S. He outlined the compulsory legislation by which landowners are either compelled to keep down malaria on their holdings, or to pay for the expenses of so doing; the 27 years of practical experience of the problem in Malaya; the organisation for control, both central, urban and rural; the possibilities of a malaria tax; the cost of anti-malarial measures and, briefly, the splendid results obtained.

This was followed by an extremely interesting account by Colonel James of anti-malarial measures in poverty-stricken regions. This was based on a report presented to the League of Nations by a special Commission appointed to study conditions in Bulgaria after the Græco-Turk war. Here the conditions were almost indescribable; for a destitute population of more than two million poverty-stricken refugees had to be repatriated on land which was practically a malarial swamp. There was no money for anything, and the situation was met—in a fashion rather characteristic of the League of Nations—by raising a loan of 2½ millions sterling in Great Britain. The problem which the Commission had to solve was the best way of expending this grant.

Briefly, the Commission came to the conclusion that the usual anti-larval methods, which have been adopted with such striking success in the Federated Malay States and Panama, were here impossible. In general they recommended three procedures; (a) the wholesale free issue of quinine by the State; (b) an educational propaganda to try and teach the people to kill off adult mosquitoes in their homes; and (c) 'bonification.' As Colonel James explained, the term 'bonification' has been much misunderstood. It does not mean anti-mosquito measures, but general engineering works intended to improve the soil and raise the economic status and physical efficiency of the population. The result of such bonification schemes in Italy and

Holland has been to reduce greatly the amount of malaria among the peasantry, in many places without appreciably reducing the prevalence of the transmitting mosquitoes—a condition of 'anophelinism sine malaria.'

Colonel James' paper was followed by one by Dr. Scharff, who dealt with the organisation of the intensive anti-mosquito campaign in the rural area of Singapore. The results of the 1922-27 campaign were explained, and a vivid picture presented of the splendid results achieved, and the economic gain resulting. Singapore, despite its situation and climate, is now almost free from malaria. The comparative cost of temporary versus permanent measures was discussed. The cost of the measures incurred has been far less than the cost of a wholesale free issue of quinine would have been.

The rubber plantations of Malaya have grappled with malaria with the greatest success. The Indian tea industry is taking active measures; the Indian railways are appointing malariologists. Malaria costs a commercial industry more financially than the saving which results from its eradication, and the planters of Malaya and Ceylon and Assam are no fools. Yet there are to-day dying villages and towns in the Punjab, which, had they been in the United States, would have imposed upon themselves a malaria tax in order to eradicate the pestilence.

In the discussion which followed, it at once became clear that the workers in the tropics largely disagreed with Colonel James' views. They were nervous in the first instance lest provincial and other administrations might take the report of the League of Nations' Commission as an excuse for reducing or abolishing anti-malarial grants. In the second place they gravely doubted the value of wholesale free distribution of quinine to control malaria, for the work of recent years has shown that the habitual taking of quinine will not protect man against infection by the mosquito; it will only render the malaria less severe when it does occur. In the third place, they doubted whether adult mosquitoes could be caught or destroyed in the dark smoke-infested huts which had been shown on the screen. Wherever anti-larval measures have been applied on a sufficiently well-organised scale, malaria has been eradicated. Several speakers emphasised that it was anti-anopheline control, and especially anti-species control that was most effective. And what has been done in Malaya can be achieved in India if only the money, men, and munitions are forthcoming.

A still further factor which was discussed by the meeting was that engineers often create malaria. When large irrigation projects are carried out without the health authorities being consulted, anopheline-breeding swamps are only too often created, with a marked increase of the malaria in the locality. One of the resolutions passed dealt with this subject and urged that all such projects should be submitted to the health authorities for consideration before they are sanctioned.

The consensus of the meeting showed very clearly that there is no simple and royal road to the control of malaria; each malarial district is a problem by itself, and what suits one area or one country may be quite unsuitable or impossible for another.

At the afternoon session of the first day—Dec. 5th—Lieut.-Col. C. A. Gill, I.M.S., read a paper on the theory and practice of malaria control; he referred especially to biological methods of control and to the value of forecasting of malaria epidemics. Dr. Strickland's paper dealt with conditions on Ambootia Tea Estate near Kurseong. Here the carrying species was found to be *A. maculatus*, a mosquito which requires clear running streams exposed to sunlight in which to breed. This species was found breeding in the hill-side streams on the estate; these ravines were now planted with jungle, which was allowed to grow. With the growth of this jungle *A. maculatus* disappeared, and with it most of the malaria on the

garden. In this instance a very simple and unorthodox procedure eradicated malaria; the cost was almost nil. Dr. G. C. Ramsay, O.B.E., read a paper on a malaria survey of a group of tea gardens in Assam. It was found that *A. minimus* and the newly discovered *A. ramsayi* were the principal carriers concerned. The latter breeds in grassy tanks, in permanent pools and in swamps with clear standing water in which grass grows. Colonel Katsuno dealt with endemic malaria as met with in Central Japan, and Mr. M. O. T. Iyengar read a paper illustrated by very fine lantern slides dealing with malaria in the lower Bengal delta. The country concerned, he showed, is absolutely flat and consists of two different types; areas with relatively dry soil where temporary accumulations of water during the monsoon form important breeding places for *Anopheles* mosquitoes and where there is much malaria; and areas which are almost perennially flooded, where there is little or no malaria. Large areas of standing water in fact are not the malarial menace to a populace that they are frequently supposed to be, and Calcutta is largely protected by the extensive inundations around the city. On the other hand should *A. ludlowi*—a species which breeds in salt water marshes, and which has been responsible for rendering the Andamans almost uninhabitable on account of malaria—ever get a grip of the environs of Calcutta, it might render the city uninhabitable.

On the second day, December 6th, Colonel James opened the proceedings by reading a paper on the habits of *Anopheles* with reference to their rôle in the spread of malaria. This largely covered the work at the British Ministry of Health which has previously been reviewed in our columns. The process of oviposition, it was pointed out, is dangerous to the adult female mosquito, and in England thus occurs in May and June especially. Towards the end of August there is an almost complete cessation of the maturation of the ova in the female mosquitoes; they survive longer, and their opportunities for infecting persons are therefore much greater. During the winter, with hibernation, the development of the malaria cycle in infected mosquitoes is delayed, but warming such mosquitoes will rapidly render them infective. It is not merely species that are important in malaria transmission, but seasonal factors concerned with such questions as oviposition and the length of life of the adult female mosquito that are important; 100 infected mosquitoes in September may do much more harm than 3,000 in June. Mr. Senior-White then dealt with the biological factors affecting the breeding of mosquito larvæ. He showed that larva-eating fish, though valuable, were not always a suitable measure for malaria control; the pH of the breeding water-supply has a correlation with the successful breeding out of the larvæ, but the correlation is a partial and not a complete one. The chief factor directly correlated with breeding appears to be the ammonia-nitrogen content of the water. As this is largely supplied by organisms of *Nitrobacter* and *Nitrosomonas* type, it may be possible to evolve a bacteriophage against these organisms, and to treat breeding grounds with it. The future of larval control appears to lie along lines of investigation of the biological factors affecting breeding of the larvæ. An exceedingly interesting paper dealing with the feeding habits of anopheline larvæ by Colonel Christophers and Mr. I. M. Puri of the Central Research Institute, Kasauli, was read by the latter author. The breeding grounds tend to become covered with a surface film of bacteria and flagellate protozoa, and the *Anopheles* larva, by virtue of its position at the surface of the water, tends especially to feed on the sub-surface film. Bacteria and algae appear to constitute its chief food supply. This paper was illustrated by splendid photomicrographs showing the larvæ in the act of feeding. Dr. Bruce Mayne then dealt with the possibility of detecting malaria-infected mosquitoes on dissection as an indication of the onset of conditions favourable for the spread of malaria. In the afternoon

papers dealing with the spleen rate in malaria and methods of measuring the enlarged spleen were read by Colonel Christophers, Major Sinton, and Major Covell.

Malaria Treatment.—The third day of the session, December 7th, was devoted to papers dealing with treatment. Colonel James read a paper dealing with the treatment of malaria in mental patients in England induced for therapeutic purposes by the bite of infected mosquitoes. This malaria is far more amenable to quinine therapy than malaria as usually encountered in the tropics. Some of the patients showed a most extraordinary delay—up to nine months or so—in developing malaria after being bitten by infective mosquitoes. Cold and exercise might affect the onset of fever. In such experimentally induced malaria, very short, three or five day courses of quinine treatment were as efficacious as the prolonged ones usually advocated in the tropics. In the discussion which followed this paper, several speakers emphasized that conditions in the tropics, where one rarely saw a case of primary malaria, but was usually called upon to treat relapsing cases, were quite different, and the general opinion appeared to be in favour of prolonged quinine therapy. Major Sinton gave an outline of his well-known work on the treatment of malaria; the administration of alkalies plus quinine appears to control the fever more effectually than any other procedure and to lead to a much smaller percentage of relapses; plasmoquine has its place in the treatment of malaria, but its administration needs to be carefully watched, as it may be toxic. Colonel Acton read a paper by himself and Major R. N. Chopra, I.M.S., on the action of quinine on the malaria parasites: the authors claim that quinine is far more active in an alkaline than in an acid substrate; that quinine in low concentration first paralyses and then kills the plasmodia. Hence it would appear that its chief action is to paralyse the young parasite forms; these fail to get a grip of the red corpuscles, are swept off into the general blood stream, caught in the capillary plexuses of the spleen, where they disintegrate. The special value of quinine in malignant tertian malaria is due to the fact that, after its administration, the maximal concentration of quinine in the blood stream—in the portal circulation—coincides with the maximal site of multiplication of the parasites. Colonel Froilano de Mello, from Nova Goa, had found Smalarina useless in the treatment of malaria, whilst Dr. K. E. Surkeb, of Pager-Alam, advocated the use of silver-salvarsan intravenously for its special action on the gametocytes of malaria parasites; it is claimed to be safer and more stable in the tropics than neosalvarsan. It is important in general to combine arsenic therapy with quinine in the treatment of malaria.

PLAGUE.

One of the most notable features in connection with the Plague Section of the Congress was the wonderful exhibit by the Haffkine Institute on this subject in the Scientific Exhibition of the Congress; this dealt with the history of plague in Europe and Asia—including many reproductions of quaint and ancient prints, and the methods of preparation of anti-plague vaccine at Parcel. The Plague Section of the Congress constituted a special meeting and combined discussion between the F. E. A. T. M., and the League of Nations Plague Sub-committee. Lieut.-Col. F. P. Mackie, O.B.E., I.M.S., dealt with the present position of the plague problem in India and elsewhere. He dealt with the different rodents associated with the epidemic spread of plague in different countries, their different ectoparasites concerned, the climatic factors, and the carrying over of epidemics; with the human factor, the history of plague in India, the value of inoculation against plague, and the possibilities attending the use of bacteriophage. Dr. Wu Lien Teh then gave a history of pneumonic plague in Manchuria and dealt with its epidemiology, pathology, and infectivity; the value of sera and

vaccines was discussed; whilst he also dealt with the perpetuation of plague in wild rodents, and especially in the Siberian marmot in Manchuria. Dr. A. N. Goyle gave an account of his work in the United Provinces; *Xenopsylla cheopis* had proved a better transmitter than *X. astia*, whilst male fleas appeared to transmit better than females. Climatic conditions under which continuous transmission was obtained had also been studied. Khan Bahadur Dr. N. H. Choksy of Bombay then dealt with 'an unrecognised type of plague'—the cellululo-cutaneous type, associated with local spreading necrosis of tissues. It constitutes about 4 to 6 per cent. of the cases seen, and has a relatively low mortality—recovery rate 37 per cent. as against one of 26 per cent. for the bubonic type.

There was a considerable discussion in the Plague Section, and many speakers took part. The account by Colonel Forster, I.M.S., of the measures taken in trying to extirpate plague in rural villages in the off season, and especially in villages infected late in the plague season, in order to prevent recurrence in the next season was of special interest.

CHOLERA.

The Cholera Section was one of special interest. It was opened by Lieut.-Col. A. J. H. Russell, C.B.E., I.M.S., who gave an account of his statistical enquiries into the epidemiology of cholera in India. He showed how in Madras Presidency there are three different areas, in which conditions are entirely different. Cholera constituted a most serious problem for India. The bulletins issued by the League of Nations indicated that at the present time India was practically the only part of the world in which cholera persisted in epidemic form, and as Bengal had been called "the home of cholera" by most writers during the past 200 years it seemed fitting that that disease should form the subject of a discussion at an international congress in Calcutta.

Continuing, Col. Russell said:—"A review of the historical records makes it evident that the disease known as cholera was familiar to the Hindus, Chinese, Arab, Greek and Roman writers of the pre-Christian era and that in India the cholera of to-day is exactly the same as it was at least 400 years ago and as it probably ever has been." Because of India's position as a source of infection to other countries it has been the unfortunate custom in discussing the epidemiology of cholera to look upon epidemics there as relatively unimportant and to devote the most time and energy to tracing the routes of spread from India to other parts of the world.

It is obvious, he said, that the epidemiology of cholera as it exists in India is the key to the problem, and it is surprising how little attention the epidemiological features of the disease have received in the past, most writers having been content either to ignore the question altogether or make a vain repetition of previously recorded inaccuracies. If the causal factors influencing the periodic outbursts of the disease in this country could be elucidated its spread to other countries would cease altogether, or in any case cease to be of any importance.

Cholera in India is a very familiar and easily recognized disease, and although many cases of diarrhoea are no doubt wrongly included, it has been found that results are not vitiated to any extent by assuming that all deaths registered as cholera are actually such. By using the statistics for different provinces it has been possible, for example, to forecast epidemics of cholera two or three months ahead of the actual outbreaks. It may, therefore, be stated with confidence that the available data are sufficiently accurate for purposes of a comparative epidemiological study and that they may permit of definite inferences being made.

A study of the annual cholera deaths over a long period of years has made it possible to divide the provinces of India into three great groups. The first group includes the provinces of Assam, Bengal, Bihar

and Orissa, and the United Provinces, where more or less uniform figures are registered annually, and where the average incidence is high. These areas are likely to be epidemic in nature. In the second group are included the Central Provinces, Bombay Presidency, the Punjab and the N. W. Frontier Province, where sudden peaks in cholera incidence occur at regular intervals. These areas are nearly free from cholera epidemics, and infection is probably always brought in from outside. The northern and central district groups of the Madras Presidency are epidemic areas, whilst the southern districts group which presents a uniform incidence might almost be included in the first group as an endemic area.

As with other epidemic diseases, cholera spreads widely and rapidly at certain periods, whilst at other times it remains dormant or spreads only sporadically and with difficulty. The regular seasonal appearance of the disease in more or less virulent form is a well-recognized characteristic of its manifestations. It has been found in nearly all the areas where cholera is epidemic, waves of the disease recur once every 5 to 6 years, while in the endemic areas a 4 to 5 years periodicity is most probable. In every case the periodograms show that cholera tends to run a more or less definite course of revival, decline and subsidence in each cycle of years.

It must not be understood, however, that cholera in India adheres to a regular cycle. As Sir Leonard Rogers has stated, the problems associated with the epidemiology of cholera are not so simple as to be explained by the cyclic trend. Koch attempted to explain this periodicity "mainly through the influence of the immunity which follows extensive ravages of the disease." Probably other factors have an equal significance, but whatever influence may be at work, it is certain that a foreknowledge of the probable advent of a periodic wave in the incidence of the disease would go far to prevent waste of efforts in unnecessary directions and at unnecessary seasons. In Madras we have for three years past made use of that knowledge with considerable success.

Proceeding, Col. Russell said: "So long as public health departments confine their attention merely to the eradication of the disease, so long will their efforts end in disappointment. The proposal to protect millions of pilgrims year after year by means of the new cholera vaccine was one that might make the bravest tremble and the boldest public health administrator submit his resignation. Inoculation against cholera is, of course, no new experiment in India, and public health authorities are well acquainted with the prophylactic value of the new cholera vaccine.

"It is obvious in any case that inoculation by itself cannot be expected to eradicate cholera unless extensive sanitary arrangements are made at important towns and trading centres. The provision of pure water supplies, rapid collection and disposal of refuse; the extension of health organisations and staffs; and the immediate notification of outbreaks of the disease are all important essentials which are receiving more and more attention from provincial governments and public health departments.

"In the great task of controlling cholera in India we need the co-operation not merely of the governments in India but of all interested in the welfare of India, and the support of such international bodies such as the League of Nations and the Far Eastern Association of Tropical Medicine will go far to ensure such advance. It ought not to be beyond the skill of man with all the weapons of modern science at his command to devise measures to meet successfully many of the influences at work, and only when these are introduced will it be possible to hope for the control and eventual eradication of this deadly enemy of mankind."

Dr. S. Kiribayashi then gave an account of the epidemics of cholera in Formosa since 1895, and

Dr. E. E. M. H. Jourdan an account of the 1927 outbreak in Tonkin. Lieut.-Col. C. L. Dunn, C.I.E., I.M.S., then gave an account of the very successful measures which he and his assistants adopted against cholera at the great Kumbh Mela fair at Hardwar in the United Provinces in 1927. In all, 90 cases occurred, and every one of them was closely investigated; it was found that the early cases were all imported from Bengal and that the Ganges water was responsible for all. Bacteriological and chemical analyses of the water from a 10-mile stretch of river were made and gross pollution with sullage water from Hardwar was found. Examination of the stools of 1,000 healthy persons and contacts showed a marked increase in the number of persons passing vibrios during the period when cholera increased, whilst flies were also definitely incriminated. Over 10,000 persons were inoculated, and the prophylactic measures advocated are the introduction of underground sewage, chlorination of the most dangerous part of the Ganges, and the use of tap water. Colonel Dunn and his staff are to be congratulated on the splendid way in which they tackled the cholera problem in connection with this great pilgrimage.

Dr. J. W. Tomb, O.B.E., then read a paper on the bacteriology and epidemiology of cholera in the Asansol Mining Settlement. This paper covered much of the ground previously reported by these authors in papers in this journal. The 'open-bowl' method of cultivation of vibrios was described, and the conversion under natural conditions of agglutinating into non-agglutinating strains. The general factors, such as the vibronic content of surface water supplies, the atmospheric absolute humidity and temperature were discussed.

A lively discussion followed. Colonel Forster agreed with Col. Dunn and Col. Russell in desiring a much larger anti-cholera organisation in India, and Col. Graham agreed with them. The League of Nations and all-Europe generally is looking to India to control its cholera problem, as this constitutes a danger to the whole of the world, and epidemics which begin in Bengal may spread as far as the Mississippi.

In the afternoon session Colonel Russell dealt with the results obtained from subcutaneous inoculation of anti-cholera vaccine and from the oral use of bili-vaccine.

He referred to the experiment carried out by the Government of Madras at the suggestion of the Office Internationale d'Hygiène Publique, and said that both the subcutaneous anti-cholera vaccine and the oral bili-vaccine conferred a high degree of immunity. He added that the risk of injury from inoculation was so inappreciable and the discomfort so uncommon that the case in favour of anti-cholera vaccine as a practical and cheap preventive measure was complete.

Bili-vaccine takes the form of tablets which are dissolved in the mouth and serves the same purpose as inoculation against cholera, typhoid and dysentery.

Experts from different parts of India took part in the discussion and narrated their experiences of how suppression of cholera has followed immediately upon the inoculation of an infected community. The consensus of opinion was that anti-cholera vaccine was one of the most valuable preventive measures.

In the course of his paper on anti-cholera inoculation Col. Russell said: For many years past the constantly recurring epidemics of cholera in India have been a matter of grave anxiety not only to the governments of this country, but to other nations of the world. While considerable attention has been given to the study of the epidemiology of cholera and many obscure points have been made clear, effective control of the disease still constitutes an extremely difficult problem, and public health workers in India are only too anxious to utilize every possible means to reduce its incidence.

When, therefore, it was suggested by the Office Internationale d'Hygiène Publique that experiments with Besredka's cholera bili-vaccine should be made in India, the Public Health Commissioner with the

Government of India had no difficulty in arranging for tests to be carried out in several provinces. With financial assistance from the Indian Research Fund Association a comparative field test of the bili-vaccine and the well-known anti-cholera vaccine was commenced in the Madras Presidency in December 1925. After 18 months' work, covering three epidemics, a report was submitted to the League of Nations, Health Section, and to the Office Internationale in July 1927, with a view to early publication of the results.

After referring to the report, Col. Russell continued: "The coefficients of correlation between treatment with vaccines and cholera attacks are uniformly negative and significant, two being as high as 0.52. Protection is therefore conferred by both vaccines, although the coefficients are not so high as those usually obtained for groups of persons protected against small-pox by vaccine lymph. The coefficients for direct contacts are all between -0.28 and -0.52. Treatment with the vaccine has, therefore, conferred a high degree of protection among persons directly exposed to infection.

Remembering the limitations, he concluded, it may be inferred that a high degree of immunity is conferred by both the subcutaneous anti-cholera vaccine and the oral bili-vaccine, but that the former is in the long run superior to the latter. In view of the fact that with the ordinary precautions the risk of injury from inoculation is inappreciable and that even transitory discomfort is uncommon, the case in favour of anti-cholera vaccine as a practical and cheap preventive measure is complete.

An interesting discussion followed in which with the exception of one, all the speakers spoke in favour of anti-cholera inoculation as a valuable preventive measure.

Lieut.-Col. W. C. Ross, I.M.S. (Bihar and Orissa), announced himself as a whole-hearted sceptic of cholera inoculation and referred to certain published and unpublished data of many years ago in support of his contention that cholera vaccine was of no value whatsoever.

Lieut.-Col. McCombie Young, I.M.S., a former Director of Public Health, Assam, said that he introduced the use of anti-cholera vaccine among tea garden emigrants to Assam about 8 or 9 years ago. In a year when cholera was greatly prevalent a quarter of a million persons were inoculated prior to their journey to Assam and the results were exceedingly satisfactory.

Dr. C. A. Bentley, Director of Public Health, Bengal, said it was most refreshing to meet a whole-hearted sceptic like Col. Ross. Nowadays when he met a critic of this sort his first question always was: "Have you ever seen any cholera inoculation; have you ever done any inoculation and have you ever been inoculated yourself?" But he invariably found that such critics could never answer any of these questions in the affirmative.

He had also a confession to make. Not many years ago, before he had seen any inoculation, he would have probably supported Col. Ross on theoretical grounds, but it was impossible to do so now. He remembered having told the head of a large firm in Calcutta when he asked for a supply of cholera vaccine for a tea garden, that inoculation was not the soundest measure to adopt. His views were quite different now, and he had been compelled to change them by the accumulated weight of evidence in favour of inoculation.

Nearly four years ago, continued Dr. Bentley, an outbreak of cholera occurred at Dogachia, a village about 20 miles from Calcutta, where the Bengal Health Association had a volunteer service for the treatment of kala-azar. Medical officers were sent to him for cholera vaccine and a few days later they asked for a further supply because the villagers from five or six villages wished to be inoculated. He was surprised at this request and went out personally to see what was happening and saw an amazing sight. An

unending stream of men, women and children were passing the tables where the volunteer doctors and their helpers were doing inoculation. He also learnt the cause of the phenomenon.

There had been five cases of cholera at the village of Narainpur before inoculation was begun. When the vaccine arrived every man, woman and child in the village was inoculated except two persons, one, a man who refused to take it, and the other, a little girl, who ran away and hid herself. Within twenty-four hours the man who refused inoculation died of cholera, and within three days the little girl, who hid herself, also died of the same disease. This fact speedily spread abroad and led the inhabitants of the neighbouring villages to ask for inoculation.

This story had a sequel. A few months ago, more than three years after the inoculation, Dr. Bentley visited the village, and was told by the villagers that there had not been a single case of cholera in that neighbourhood since the inoculation, although formerly they used to get cholera every year. There was a still further sequel. About a fortnight ago a petition had been received from the villagers stating that after long immunity from cholera owing, as they stated, to the former inoculations, the disease had again appeared, and imploring that arrangements should be made to reinoculate them once more. He was glad to say that the same agency, the Bengal Health Association, undertook this task and within a few days 1,500 people were inoculated with the result that cholera disappeared.

Referring to another instance showing the value of cholera inoculation, Dr. Bentley said last year a village in the district of Rajshahi, inhabited by Hindus and Mohammedans, was attacked with cholera. A doctor was sent there with vaccines and the Hindus readily took inoculation with the result that cholera ceased among them. At this time communal trouble was prevalent and because of this the Mohammedans refused at first to take inoculation from the doctor who was a Hindu. When, however, they saw that the disease had ceased among the Hindus after inoculation, while they were still being attacked, the Mohammedan men took inoculation, but refused it for their womenfolk on account of purdah prejudices. But when the doctor was about to leave the village the Mohammedans changed their minds and implored him to remain and inoculate their women also. The doctor completed the inoculation and the epidemic promptly disappeared.

Instances of this nature which could be multiplied indefinitely had compelled him to change his former attitude of hostility to cholera vaccine, and he now considered that this was the most valuable single method of combating cholera.

Col. de Mello (Goa) referred to the wonderful results which had been achieved by cholera inoculation in Goa. He said that formerly they had never been able to control these epidemics, but now with cholera vaccine they could combat them easily and quickly. The results were so efficacious that the Government had now made cholera inoculation compulsory in the Army, among the police, and for all cholera contacts throughout the country.

Replying, Col. Russell said about 100,000 inoculations had been performed in Madras city within a month, and as far as he was aware, there had not been a single case of death from cholera among the inoculated. The reaction was so trifling as to be negligible.

Referring to his experience in rural areas, he said that about half a million inoculations had been performed during the last three months and the results had been invariably excellent, so much so that he could unhesitatingly state that in his opinion cholera inoculation was one of the most effective means at their disposal for controlling and preventing the disease.

A very interesting paper in the Cholera Section was one by Dr. B. B. Brahmachari, Assistant Director of

Public Health, Bengal, on the relationship of non-agglutinating vibrios to the true *Vibrio cholerae*. In an endemic area 68 non-agglutinating strains of vibrios had been isolated and their properties investigated. On inoculation into rabbits a typical anti-serum against these strains was produced, but, after intravenous passage through the rabbit some of the non-agglutinating strains became transformed into typical *Vibrio cholerae* and showed agglutination to anti-serum of the true Koch's vibrio. Other similar strains on sub-passage on culture media also became transformed into the true Koch's vibrio. Dr. Brahmachari's paper—if his results are confirmed—is one of the very greatest importance in connection with the ætiology of cholera. Many workers have for years tried to prove the conversion of non-agglutinating strains into the true Koch's vibrio, but, whilst previous workers—such as Tomb and Maitra—have succeeded in converting the true Koch's vibrio into a non-agglutinating type, apparently no one has previously seen the converse transformation, of the non-agglutinating strain into the true Koch's vibrio.

KALA-AZAR.*

On Thursday morning, December 8th, the meeting of Section IV was devoted to kala-azar. Col. S. P. James presided and the meeting was opened by Lt.-Col. R. Knowles reading a paper on "The Kala-azar Transmission Problem and the Factor of Resistance." He commenced by giving a short historical account of the various facts which had led to the suggestion that sandflies transmitted *Leishmania*. Wenyon in 1911 discovered that 6 per cent. of wild sandflies in Aleppo were infected with a natural herpetomonad. In 1914 Mackie discovered a herpetomonad (? *Bodo*) in a number of specimens of *Phlebotomus minutus* in Assam. In 1915 the Sergent brothers, Lemaire and Senevet attempted, but failed, to transmit oriental sore by means of *P. minutus*. In 1919 Acton showed that the distribution of sandfly bites corresponded with the distribution of oriental sores on the human body. In 1921 the Sergent brothers, Parrot, Donatien and Beguet caused an oriental sore in a person living in a non-endemic area by the inoculation of an emulsion of sandflies caught in the endemic area. In 1920 Cerqueira showed that the lesions of espundia followed at the sites of sandfly bites, and in 1922 Aragao found herpetomonads in wild sandflies of the *P. intermedius* species.

In 1922 Napier analysed the season of onset of kala-azar and found that the largest number of cases commenced in the months of November to February. This indicated July to October as the months when fresh infections are most likely to take place. McCombie Young reported similar findings in certain districts in Assam. In 1923 Napier investigated the places of residence of the cases in Calcutta and found that there was an endemic focus of the disease in Ward XIV in Calcutta city; on the other hand he found that in the North of Calcutta numerous cases were imported, but that only very rarely did a fresh case originate from this part of the town. After an extensive epidemiological study of the disease, Napier enumerated 21 cardinal points as being the necessary characteristics of the vector of kala-azar, whatever it was. The *Culicoides* and the sandflies are the only insects that fit in with these 21 cardinal points. In Calcutta only three species of sandfly were found, *P. squamipleuris* which was exceedingly rare, *P. minutus* which was apparently a pure lizard-feeder, and *P. argentipes* which was thus the most likely vector. This species was found in very large numbers in the endemic area during the monsoon. Feeding experiments with laboratory-bred *P. argentipes* on kala-azar patients were

undertaken with almost immediate success. Knowles, Napier and Smith in December 1924, published a paper in which they were able to show that the parasite of kala-azar developed and multiplied in the gut of this sandfly very readily. In the following year this observation was confirmed by the Kala-azar Commission, working in Assam.

From this time onwards rapid progress was made, chiefly as a result of the splendid work of the Kala-azar Commission. The life cycle of the parasite in the fly was worked out by Shortt, Barraud and Craighead; they discovered a wild fly infected in Nature, and proved the infectivity of the flagellate form. They demonstrated a massive infection of the buccal cavity of the fly at the 7th and 8th days. It was thus obvious that *Leishmania* infection in the sandfly behaves very differently from a natural flagellate infection in an insect; this always progresses towards the rectum and is transmitted to another insect by means of the faeces.

Parallel work was carried out by Adler and Theodor in Palestine with the sandfly *P. papatasi* and the *Leishmania* of oriental sore.

In March 1926, the position was very favourable, only one final proof being wanted, namely the actual transmission of the disease from one person to another by means of an infected sandfly. Yet, despite an enormous amount of work by both the Kala-azar Commission in Assam and the workers at the Calcutta School of Tropical Medicine, this final proof has not been forthcoming.

Why? Colonel Knowles said that he believed that the reason was that man—and still more so the experimental animals—instead of being very susceptible to infection by the parasite of kala-azar were actually very resistant to it. Even the Chinese hamster had proved very resistant to infection in India where it does not hibernate.

He reviewed the evidence in favour of this view:—

Epidemiological. The curiously slow mode of spread of even epidemic kala-azar. The association of epidemic kala-azar with lowered vitality or debilitated state of the people. The Nowgong epidemic followed after the Assam earthquake; and the recent recrudescence in Assam followed close after the influenza pandemic.

Clinical. The modes of onset of kala-azar; the frequent commencement of the disease as a true infection with *B. typhosus*, or as a true malaria with malaria parasites in blood films; followed by febrile relapse with *L. donovani* culturable from peripheral blood; the contrast between malaria as a disease of sthenic individuals and kala-azar as a disease of debilitated individuals; the hypoadrenia of kala-azar.

Dermal leishmanoid. There is a marked contrast between it and kala-azar, though both are due to *L. donovani*. The pigmentation of the skin in kala-azar is an indication of adrenal insufficiency.

Experimental.—The very great difficulty and uncertainty of inducing true kala-azar in experimental animals is very marked, even after injection of massive doses of virus. The frequency of transient and symptomless infections in animals: the much greater frequency of failure of infection to take at all.

It has been suggested that in endemic areas mankind may get infected wholesale with *L. donovani*. In the vast majority of persons the parasite may never cause any symptoms at all; several remarkable cases are reported in the literature of very prolonged incubation and latent periods of kala-azar. In some persons with high resistance (probably associated with hyperadrenia) the infection only produces dermal leishmanoid. In a relatively few persons, whose resistance is unduly lowered by high food prices or intercurrent disease, the parasite causes true kala-azar. Hence his belief that to continue feeding hundreds of infected sandflies on healthy volunteers or experimental animals may lead us nowhere. We want a study of the nature of, and the factors underlying, this resistance and to find

* By Dr. L. E. Napier, Kala-Azar Research Worker, Calcutta School of Tropical Medicine.

out how to break it down. Recently attempts had been made in Calcutta along these lines; sub-total thyroidectomy and adrenalectomy have been performed on experimental monkeys.

Before the last and final proof that kala-azar is transmitted by sandflies is afforded, this factor of resistance will probably have to be studied and overcome. This involves team work in a large institution, and the services of a biochemist.

Maigor H. E. Shortt then read a paper on "The Life-History of *Leishmania donovani* in its insect and mammalian hosts."

"The life-history of *Leishmania donovani* can be represented diagrammatically by a figure 8, one circle corresponding to the cycle in the insect, the other to that in the mammal, while the central point of construction, the only point where the two cycles meet, represents the bite of the fly, either at the time of ingesting the parasite from the mammalian blood or of returning it to a fresh mammalian host. The two cycles will be described separately, and the act of biting of the fly, the only point where they met, will then be considered.

Life-cycle in *Phlebotomus argentipes*.

The sandfly at its initial feed ingests Leishman-Donovan bodies (type I) from the peripheral blood of a case of kala-azar.

After twenty-four hours the original compact Leishman-Donovan body has increased considerably in size. The flagellar vacuole is a prominent structure, the cytoplasm stains a deep blue with the Romanowsky stains, and usually contains vacuoles. The flagellum is unformed or rudimentary (type II). A flagellate division forms may be present. All the forms are immobile.

After forty-eight hours the swollen affagellate forms have become somewhat elongated and have developed flagella, the latter being often in a rudimentary stage. The flagellates are sluggish motile but incapable of active translatory movement. The types of flagellate present are type III, stumpy or rounded flagellates, and type IV, immature or larval forms. Division forms are numerous.

Three days after the fly's feed one finds the first appearance of elongated free-swimming flagellates. These are chiefly of type Vb. Types III and IV, already present on the second day, are greatly increased in numbers, and division forms are much in evidence. A few "rosettes" of flagellates may be present. The free-swimming flagellates show intense activity which would enable them to penetrate to any situation in the gut. The flagellates appear to be distributed indifferently throughout the midgut. The end of the third day marks a definite stage in the life-history since now most of the forms of flagellate present in the later stages have already made their appearance.

From the fourth day onwards there is seen intensely active multiplication resulting in an enormous increase of all the types of flagellate already mentioned. A new factor of importance is also now in evidence. This is a progressive concentration of the flagellates in an anterior direction. From this stage onwards the advance of the infection is directed continuously forwards towards the biting parts.

By the fourth or fifth day the fly will usually have taken its second feed. At this stage it will be convenient to describe the appearance of a heavily infected fly on about the fifth day after its initial feed. If the entire alimentary canal be dissected out the conditions now to be described will be found.

The anterior end of the midgut, especially near the proventricular region, will be found to be swollen out by a solid refringent mass of flagellates. The centre of this mass will appear practically immobile but its periphery posteriorly will exhibit a seething motility. The reason for this is that so closely are

the flagellates packed that only those on the outskirts of the mass have any opportunity to move. A varying number of actively free-swimming elongated flagellates will be in evidence posterior to the main mass. The flagellates near the proventricular region and those near the periphery of the mass more posteriorly will be seen to be attached by their flagellar ends to the walls of the gut. These sessile forms are chiefly of types III and IV and, owing to their cramped situation, are not the source of the seething motility mentioned. This is produced entirely by the forms which are near the periphery of the main mass and so can project into the lumen of the gut. These forms appear to be mainly of type V.

The anterior extremity of the infection at this stage reaches the oesophagus of the fly, but in some cases may extend as far as the posterior expanded portion of the pharynx. In the midgut immediately posterior to the anteriorly placed mass, there are numerous free-swimming elongated flagellates, but these decrease in concentration posteriorly and the posterior half of the midgut and the whole of the midgut are practically free of flagellates.

From the condition just described, which is that reached by the fifth day after the initial feed, there is a progressive extension anteriorly of the main flagellate mass, until by the eighth or ninth day after the initial feed it has reached the mouth proper of the fly, and the most anteriorly placed flagellates are projecting into the pre-stomum. The main mass of the flagellates as it progresses anteriorly by growing along the pharyngeal and buccal cavities practically occludes the lumen of the alimentary canal, especially in its narrower portions. The progressing anterior extremity of the main mass has usually located in front of it a few elongated free or semi-detached flagellates, since a free surface always seems to encourage the production of the more elongated forms. The extent and rapidity of the development here described depend to a great extent on the initial number of parasites ingested, the larger the number the sooner the infection of the alimentary canal is complete. An average time table, however, for the anterior portion of the main growth would be as follows:—

Proventricular region, fifth day.

Posterior part of pharynx, sixth day.

Junction of pharynx and buccal cavity, seventh day.

Invasion of buccal cavity, eighth day.

Anterior end of buccal cavity, ninth or tenth day.

Besides the alimentary canal proper the flagellate infection may invade the Malpighian tubules, where flagellates in small numbers may be seen, and the oesophageal diverticulum which may be, and in heavy infections usually is, the seat of a massive growth of flagellates.

Life-cycle in the Mammalian Host.

If a fly which is infected to the extent described in the last section were to feed, it would appear necessary that some at least of the flagellates blocking the alimentary should be extruded before the blood cells could pass up the proboscis. Presuming, then, that this takes place, the sequence of events following the bite of the fly may be described as follows:

The flagellates ejected into the wound are engulfed, probably singly, by endothelial cells derived from the blood capillaries or lymph channels, thus gaining an intracellular habitat.

In the process the flagellate loses its flagellum and its body rounds up into the typical Leishman-Donovan form.

The endothelial cell gains the blood stream and may be carried to any part of the body but the sites of election for its lodgement are in the order given, spleen, liver and bone-marrow.

The intracellular Leishman-Donovan body now commences to divide by binary fission into two individuals.

Multiplication proceeds with the production of four, eight, sixteen individuals up to the capacity of the invaded cell to contain its load of parasites.

A point is finally reached where the endothelial cell can expand no further and is ruptured, releasing the contained Leishman-Donovan bodies.

These are taken up afresh by new endothelial cells of the tissue in which they are lying, and the process is repeated until finally an intense infection of the endothelial tissue of the whole organ may result, accompanied by an increase in size of the organ.

Some of these Leishman-Donovan bodies liberated from the tissue endothelial cells of the organ involved may be taken up by endothelial cells or mononuclear cells of the blood capillaries, thus giving rise to the presence of parasites in the peripheral blood of the mammal.

From the peripheral blood the parasites are again taken up by a sandfly at its feed and the cycle in the insect is repeated.

With regard to the method by which the flagellates in the sandfly are transferred to the mammalian host, if we take the prestomum of the fly as the limit of anterior progression of the flagellates, we find that the latter have still to traverse the whole length of the proboscis in order to gain access to the wound.

It is almost certain that the individual flagellates could not swim along the whole length of the proboscis in a comparatively short time to gain access to the wound. This would imply the presence of a fluid medium to swim in, and a rapid and continuous progression of the flagellates in one direction. In other words the parasite does not possess its flagellum in order to swim into the wound.

As the narrow parts of the alimentary canal of the fly in its head are completely blocked with flagellates, it follows that the blood cells cannot enter until the blocking plug is ejected. This must necessarily take place in an anterior direction where the resistance is least. Therefore the flagellates probably enter the wound in the form of a plug and as the result of an expulsive effort of the fly rather than by any volition on the part of the flagellates.

Dr. C. W. Young from Peking read a paper on kala-azar in China.

He gave a very brief resumé of the work that he and his colleagues had carried out in China during the last four years. He described their early search for a possible rodent carrier and their discovery that the hamster was very susceptible to the infection. One infected hamster has been found in Nature. Many attempts were made to transmit the disease from one infected hamster to an uninfected one by means of bed-bugs and other insects without success. The success of the Indian workers led them to investigate the sandflies of China. Three species were encountered, *Phlebotomus major*, *P. sergenti* and *P. perturbans*; when a number of flies of either of the first two species were fed on an infected hamster a certain percentage became infected with the parasite. The third species, however, completely failed to transmit the disease to a previously uninfected hamster by means of the bite of these infected flies. In China they had never infected a sandfly by allowing it to feed on an infected human being suffering from kala-azar.

He said that in China the disease was not a house infection in the way that it appeared to be in India; seldom was more than one case observed in each house. But there are many points in common between the epidemiology of the disease in India and in China; for example, it is confined to low lying areas and to alluvial soil, and is a village disease rather than a town disease.

Dr. Young did not appear to think that the disease was transmitted by a sandfly in China.

The subject of kala-azar transmission was then thrown open to discussion. A number of members

joined in this discussion. Dr. Brug said that numerous cases had been reported from Java but that they were all amongst Indians who had come from one or other of the endemic areas in India; also he observed that sandflies were rare in Java. Colonel Christophers said that it was disappointing that the final proof was so long delayed, but that it was not a time to abandon the sandfly theory; we ought rather to concentrate all our energies on obtaining the final proof that the sandfly is the transmitter. Major Shortt said that there were one or two of the "21 cardinal points" with which he did not agree and he pointed out that *Phlebotomus argentipes* has recently been found in Sanawar, above the 1,500 feet level. Dr. L. E. Napier said with reference to his "21 cardinal points," as Colonel Knowles called them, they were not compiled from an observation of the behaviour of sandflies but from a study of the epidemiology of the disease. Some of them were probably wrong and would have to be modified. It was true that no insect fitted in exactly with the 21 points, but the sandfly, and possibly the *Culicoides*, fitted better than any other insect. He would reply to this criticism "Well, if you know a better insect, go to it." Lieut.-Col. W. C. Ross, I.M.S., thought that there was much too much of this laboratory investigation. The problem would not be solved by looking down a microscope. What was wanted was a much wider view of the subject. No epidemiological work had been done and the present workers on the subject did not appear to have a mind above the sandfly, which incidentally they had so far failed to prove was the transmitter. Now he had been carrying out some epidemiological investigations, and had made some important discoveries; the disease was much more common in Bihar amongst Mohammedans than amongst Hindus. Was it conceivable that a sandfly could distinguish between a Hindu and a Mohammedan? He asked us! But, he said, were the feeding habits of the Hindu the same as that of the Mohammedan? No, the Hindu prepared his own food, whereas the Mohammedan did not do so. Furthermore he, Colonel Ross, had found that the disease was more common amongst the more well-to-do who lived in houses with latrines than amongst the poorer who live in huts and have no latrines. Surely these facts should give some clue as to the means by which the disease is transmitted. Others, including Professor Stephens, Colonel Megaw and Dr. Brahmachari, spoke on the subject. Colonel James then called upon Colonel Knowles to close the discussion.

In rising to close the discussion, Colonel Knowles said that he was sorry to see that the soil contamination theory, which he had thought to be as dead as the Dodo, had had so much support at the meeting. That theory had retarded progress for twenty years. The Assam doctors had always claimed that there was a close association between the spread of kala-azar and soil pollution, and they were right; but the association was not a direct one, but an indirect one through the habits of the sandfly species concerned. Colonel Ross had asked how was a sandfly to discriminate between a Mohammedan and a Hindu. Well, curiously enough the reply was that it could and did so discriminate. (He hoped it had not been infected with the communal virus!) The serological studies of Major Lloyd and Dr. Napier had shown that *P. argentipes* very much preferred feeding on cows to feeding on man. In Northern Calcutta the population were nearly all Hindus, and practically every household kept a cow. *P. argentipes* requires polluted soil in which to breed. In Northern Calcutta the *argentipes* were breeding in the cowsheds; when the adult insects emerged, they took to feeding on cows, and did not bite man. Hence, although fresh infection in the form of patients coming into the city for treatment was continually being imported into Northern Calcutta, the disease did not spread there. The cow protected man in that area. On the other hand, in the endemic area in and around ward 14, the population were chiefly Mohammedans, and Anglo-Indians; these people did not keep cows, and cattle

were scarce. Here the *argentipes*, which swarm in that area, and especially so during the monsoon, breed out in the soil of courtyards contaminated with the droppings of fowls and ducks, which these people keep in large numbers. When the adult insects emerge, there are no cows for them to feed upon; hence they take to feeding on man, and hence kala-azar spreads in that area. Doubtless some such similar explanation could be offered to account for the difference in the prevalence in the disease in the two communities in Bihar. (At this point Colonel Ross interjected the remark that in Bihar Mohammedans also keep cows.)

The suggestion that the epidemiology of the disease has not been studied is entirely unjustifiable. Colonel Ross' observations are interesting, but each one of them has already been made by other workers; the greater prevalence of the disease amongst Mohammedans has been repeatedly noted, but it is not a constant feature of the disease in all areas. The Annual Reports of the Directors of Public Health in Assam and Bengal during the last 20 years have devoted a considerable amount of space to the epidemiology of the disease; Colonel Mackie studied the epidemiology of the disease in Assam many years ago, and recently Dr. Napier has contributed two big epidemiological papers. Colonel Christophers considered very carefully the contamination theory before taking up the sandfly work, but he discarded it. Colonel Ross does not perhaps realise that the sandfly hypothesis owes its origin to epidemiological observations chiefly made in Calcutta.

The position thus is that it is almost certain, but not yet finally proved, that kala-azar is transmitted by the sandfly. It is not easy to see what protective measures can be taken against this insect. In the first place, however, the insect only becomes infective under monsoon conditions, and therefore protective measures can be confined to the months from July to November. The adult insect bites readily at night, also during the daytime in a darkened and quiet room. No mosquito net will protect against it, and a net of sufficiently fine mesh to give protection would be unbearably hot. In the infected areas in Calcutta city the electric fan is the best measure against kala-azar, for sandflies are exceedingly susceptible to draughts, and no *P. argentipes* would bite a person sleeping under a moving fan. Residence on the ground floors in the infected area is dangerous, but the upper storeys are safe for the sandfly does not rise much above the ground floor rooms. The suggestion to keep a cow in one's bedroom as bait for the sandfly is an impracticable one. With regard to fumigation, the work of Pringault has shown that vapourised cresol is most effective against sandflies.

Ultimately, it will probably be found best to try to destroy the sandfly ova and larvæ in the polluted soil in which they breed out by treating it with chemical reagents, rather than to try and take measures against the adult insect. Also it goes without saying that the higher the standard of household and soil cleanliness maintained, the less chance there will be for *P. argentipes* to breed. In Assam the European tea planters are to some extent protected because their bungalows are built on elevated *changs*, and so partially elevated above the sandfly zone.

So far from being hopeless, the kala-azar transmission problem was now almost cleared up. It had taken twenty years of work by some of the best trained investigators in India to solve it, but he felt sure that the end was near.

Dr. B. M. Das Gupta then read a paper on "Experimental transmission of Oriental Sore to laboratory animals." A young guinea-pig and two English mice were inoculated intraperitoneally, subcutaneously and intradermally, respectively, with a 2-weeks old *Leishmania tropica* culture. All these three animals were found to have developed visceral infection when killed and examined 93 days later. In the case of the guinea-pig, a distinct papule appeared at the site of inoculation

21 days after and this persisted, but did not ulcerate, till the animal was killed. Scrapings from the nodule examined from time to time showed scanty streptothrix but no *Leishmania*. The second mouse showed a diffuse induration around the site of injection soon after which disappeared within a week.

Lt.-Colonel H. W. Acton, I.M.S., read a paper by Major R. N. Chopra and himself on "The action of the Pentavalent Compounds of Antimony on the *Leishmania donovani* Parasite."

"During our researches on the action of specific drugs, one of us (R. N. C.) noticed the marked effect that the pentavalent compounds of antimony, especially Urea Stibamine and Amino-stiburea had in causing marked alterations in the volume of the spleen. We considered that this action may in some way account for the better therapeutic results obtained clinically by these two compounds. We decided to investigate how these compounds acted on the parasite and bring about a cure of the disease. We found that *Paramacium caudatum* could live for hours in a solution of 1:100 Urea Stibamine, whilst flagellate cultures of the *Leishmania donovani* could survive for 10 minutes in a 1:25 concentration without being killed, so that their action would appear not to be a direct action. Napier had noticed that a good number of his cases of kala-azar, even after a course of these newer pentavalent compounds were still positive on spleen puncture or culture, and often without any further treatment went on to a permanent cure. They, therefore, stimulated some tissue in the body, and thus brought about a cure, although further treatment was not given to the patient. The so-called immunity that is seen after a course of Bayer's No. 205 against trypanosomiasis appears to be somewhat similar in nature to the effect produced by these compounds of antimony. In the case of Bayer's No. 205 it is considered that the drug stimulates the reticular-endothelial tissue. We will review our clinical and experimental data before we attempt to discuss the action of these compounds. We know that the parasites multiply chiefly in the spleen, liver and bone-marrow and to a lesser extent at other sites, and invade the endothelial cell of the reticular-endothelial tissue in these areas. When they come into the blood stream they may be engulfed by the leucocytes and destroyed by these cells. Muir, Rogers and others have shown that any drug or condition that causes leucocytosis, for example injections of turpentine, an attack of cancrum oris, etc., helps to bring about a cure. In kala-azar the bone-marrow function is depressed, as is evidenced by the marked leucopenia present, viz., 2,000—3,000 leucocytes per c.mm.

We found that these antimony compounds had the following action on the different tissues of the body.

(a) There was a great increase in the volume of the spleen, with very marked rhythmic contractions.

(b) They stimulated the bone-marrow, as the leucocyte count was increased from 2,000—3,000 per c. mm. to 7,000—9,000 per c. mm. after a course of treatment.

(c) Stimulated the function of the adrenal medullary tissue because, (i) we found the drug useful in chloasma (due to hypoadrenia) whether the cause was due to kala-azar or not. (ii) The adrenal content was higher than in normal animals after a course of treatment. (iii) Occlusion of the adrenal vein prevents the contractions of the spleen; and (iv) the results of the adrenalin test in patients before and after treatment. Unfortunately we have as yet not been able to work out the distribution of antimony in the different tissues, nor the rate of its elimination from the body: two important factors that may throw some light on the so-called resistant cases of kala-azar, which may be due to these factors, or to the failure of the tissues to respond to the stimulation by antimony.

We therefore consider that the *Leishmania* parasite of kala-azar is destroyed in the following ways, by (a) Leucocytosis and phagocytosis. Owing to the rhythmic contractions of the spleen many of the heavily

infested endothelial cells burst and set free the parasites. This can be demonstrated clinically—in the use of antimony as a provocative test. The parasites are engulfed by the polymorphonuclear leucocytes and destroyed—such is the fate of some of the parasites.

(b) Diminished cell permeability. The hyperadrenia that is produced causes a marked dilatation of the vessels of the liver and spleen pulp, which means that the rate of diffusion from the tissues is greater than the rate from the vessels—as is shown by an increase in the blood sugar, etc.; this can be shown clinically. Diminished permeability of the cells means that less food is available for the parasites, consequently the rate of reproduction is markedly diminished, and the parasites are slowly starved to death. This is probably the most important factor that brings about cures.

As no members appeared to wish to discuss these two papers the meeting was then closed.

There were a number of interesting papers which had to be taken as read as the time was so short; amongst these were included four papers on the pathology of kala-azar by Drs. Cash and Hu of the Peking Union Medical College. These papers were received after the programme of the meeting had been drawn up.

LEPROSY.

This Section met on Thursday, December 8th, and twelve papers of much interest were read. Dr. E. Muir of the Calcutta School of Tropical Medicine opened the general discussion on the treatment and prevention of leprosy. 'It cannot be claimed as yet,' he stated 'that we have a specific cure for leprosy, in the sense that the salvarsan derivatives are a specific cure for syphilis, but this is no reason for adopting the despondent attitude taken up by many, who declare that leprosy is incurable and refuse to use any remedies against it.

Whenever the treatment of leprosy has been taken up seriously and intelligently, large numbers of patients have lost all active signs of the disease, and year by year the period is lengthening during which they have remained clinically well.

Apart from the personal relief that such patients experience, it must be remembered that through their treatment and clinical recovery we are shutting off in the most effective way the main avenues of infection. If, while practically nothing was being done to stamp out leprosy, the disease was apparently at a standstill, neither increasing nor diminishing, surely the training of medical men in leprosy treatment and the general adoption of the most effective therapeutic measures must lead to marked diminution of its incidence.

It is a poor economy that refuses the half loaf because the whole loaf is not available, and I think that we have certainly got the half loaf in the form of effective treatment, giving good results in the large majority of cases, even though the whole loaf of a specific is still wanting.

The causal organism in leprosy appears to lie halfway between ordinary bacteria and the mycelium producing actinomycetales. In consequence it may be attacked by means of vaccines with the object of causing immunity, and also by means of chemotherapeutic remedies which have the effect of breaking up lepromata and allowing the tissues of the body to destroy the bacilli.

At the same time, as in all other chronic diseases for which a specific is lacking, the condition of the body and its general resistance are of first class importance, and no line of treatment which neglects these factors is likely to be generally effective.

Of chemotherapeutic remedies the most generally adopted are the oils of the *hydriocarpus-chaulmoogra* group, and their preparations. The methods of administering these are many—oral, by inunction, by the

subcutaneous, intramuscular and intravenous routes. After trying out all these we have found the intravenous injection of the sodium salt the most simple and effective, and it certainly is the most popular with patients.

This method of administration which was first adopted by Sir Leonard Rogers was given up because of the blocking of the veins which soon occurred, but a new method by which the patient's blood is mixed with a 2½ per cent. solution of the salt in the syringe before injection has done away with this difficulty. This method of administration is practically painless, a very important matter when it is considered how long patients have to endure treatment.

Another mode of treatment is to inject the pure sterile oil prepared from fresh seeds. When the oil is fresh and carefully prepared it is not painful to any marked degree, and patients stand it well. Both the methods above mentioned are cheap, an advantage which is not inconsiderable, when large numbers of poor patients have to be treated. The ethyl esters, generally given intramuscularly have in our experience been found more painful, but equally effective. They have the comparative disadvantage, in a poor country like India, of being more expensive.

Other drugs used in leprosy are some heavy metals, especially antimony and copper. Much of the benefit observed from their use is probably of the nature of limiting and clearing up reactions, although there are indications that some copper preparations may be very useful in the destruction of the disease.

After describing the effect of other drugs on leprosy, making special reference to potassium iodide, the lecturer said:—

As in all chronic diseases, the general health of the patient must be maintained. The removal of accompanying and predisposing diseases, the regulation of diet, exercise, bowel and other sanitation, favourable hygienic and climatic conditions and, most important of all, a cheerful and hopeful mental outlook are details not one of which can be neglected in the fight against leprosy.

A very important point in the treatment of leprosy is the study of each individual case. Mass treatment will not give the best results. Frequently improvement is rendered impossible by some careless habit or indulgence of the patient and these must be sought out and corrected if possible.

With regard to the prevention of leprosy, while forcible segregation may be effective in certain small isolated areas with a paternal or autocratic government, such a method cannot be applied to India effectively except in a few cases.

Two of the great stumbling-blocks in the way of dealing with leprosy have been its supposed special connection with the anger of the gods and the supposition that it was irremediable. These have driven patients to hide their "taint" as long as possible and have depressed them mentally and physically, thus causing more rapid increase of the disease. The declaration that leprosy is remediable and the placing of the means of remedy within the reach of all by training doctors and organizing treatment centres are likely to be the most effective means of prevention of leprosy in India.

The fact that within 19 days of opening a treatment centre in a rural area in the Bankura district 250 patients suffering from leprosy were attending, and that once such a centre is opened and conducted by a suitable and well trained doctor the patients continue to attend though many of them have to walk 15 or 20 miles is one of the best proofs that could be desired that leprosy is remediable.

For such centres we have found the iodide treatment the most effective and with this are combined small injections of *hydriocarpus* oil which render the

treatment more active and please the patients who are disappointed if they do not get them.

One great advantage of such centres is their co-operative inexpensiveness as compared with the foundation of asylums and colonies and they are a much more effective means of reaching early cases. They also serve as centres of propaganda and demonstrate the dangers of infection and the methods of avoiding it while patients as they recover prove to their associates the remediability of the disease.

Other papers presented at the Leprosy Section were those by Major Labernadie on leprosy in Pondicherry: on the potassium iodide treatment of leprosy by Dr. Muir; on the value of an autolysate of tubercle bacilli in the treatment of leprosy by Lieut.-Col. R. Row, O.B.E.; and an interesting survey of leprosy as it occurs in Travancore by Dr. Raman Tampi. Dr. J. M. Henderson, who has been appointed to work at the Calcutta School of Tropical Medicine under the British Empire Leprosy Relief Association, dealt with the hematological aspects of the potassium iodide treatment of leprosy, and showed how marked a leucocytosis is produced by this intensive course of potassium iodide treatment. The rôle of antimony salts and of adrenalin in controlling the reactions produced in the treatment of leprosy by other drugs, or spontaneously, was also the subject of a paper by Dr. Muir.

Tuberculosis, as a subject akin to leprosy, was dealt with in several papers. Sir William Wanless of Miraj stressed the greater prevalence of intestinal tuberculosis in India as compared with Europe, and the great opportunities for surgical treatment of this condition. Dr. A. C. Ukil gave a resumé of his studies of tuberculosis in Bengal: in general it may be stated that children in India are relatively free from tubercular infection and give a negative von Pirquet reaction. Adults, however, are heavily infected, and the type of organism isolated is almost always of human and not bovine type. Females are more frequently infected than males, and social conditions, housing, and the purdah system explain the very great prevalence of pulmonary tuberculosis in Indian cities. The relative incidence of different types of tuberculosis—surgical, bone and gland infection, pulmonary and other types, and the age incidence—was discussed.

The same author also read a paper on the prevention of tuberculosis in India. He said that the problem of tuberculosis had now assumed an international aspect and was very important to India with her land and maritime relations with other countries.

"Asiatic countries are still much less infected than those of Europe and America. As a cause of morbidity and mortality tuberculosis is one of the most important of diseases. The incidence of the toll of leprosy in India is much less in comparison with that of this socio-economic disease. Yet its claims have not attracted the measures of attention it deserves from medical men as well as the State. It will be to the interest of all the countries to co-ordinate their efforts in the anti-tuberculosis campaign."

He suggested that any scheme for combating tuberculosis must consist of directly attacking the contagion by early diagnosis, and spotting out the diseased and isolating them in special hospitals and sanatoria, their after care and the preservation of infants and non-immunised by vaccination, isolation and other methods.

Attention should also be paid towards removing the factors which favoured contagion, namely, raising the standard of living and the hygienic standard of the home by ensuring cleanliness, plentiful supply of fresh air and sunlight. He also suggested the modification of the Factories Act to provide for compulsory health insurance and the enactment of laws for the compulsory health insurance of clerks, menials, teachers, and other classes of workers, and finally the co-ordination between the different anti-tuberculosis organizations.

NUTRITIONAL AND DEFICIENCY DISEASES*

This Section was remarkably popular, the room provided for its meetings proving entirely inadequate for the accommodation of the large numbers who desired to attend.

Lieut.-Col. R. McCarrison, C.I.E., I.M.S., in his opening paper dealt with the minor manifestations of ill health which occurred in human beings who were fed on unsatisfactory diets, as well as with the more pronounced conditions like night blindness, polyneuritis, beriberi, pellagra, scurvy, rickets, sterility, anemias, gastro-intestinal disorders, stone in the bladder, etc. Among his laboratory fed rats the controls which had a suitable diet showed a mortality of 1 per cent. against 31.4 per cent. among rats kept under similar conditions on faulty diets of various kinds. Pneumonia, gastro-intestinal infections and heart disease were the chief causes of death. It is believed that the same state of affairs occurs in human beings and that such diseases as tuberculosis, leprosy, cholera and malaria take a much heavier toll from those whose diets are insufficient in any respect.

Emphasis was laid on the ill effects of lack of balance in the diets; hyperplastic goitre may result from excess of butter in the food, colloid goitre from excess of lime, stone from excess of oatmeal or white flour. In these cases the addition of counterbalancing substances such as iodine or milk neutralizes the ill effects. The diet of the Sikhs was found to be superior to any synthetic diet which could be devised, in spite of the addition of yeast and cod-liver oil to the artificial diet.

It is believed to be impossible to do harm by excess of vitamins in the diet, provided they are taken in natural food-stuffs, but the amount of vitamins required depends on the size of the animal, the period of life and the composition of its food. Col. McCarrison referred to the interesting work of Smith and others who showed that deficiency of vitamins caused an increased susceptibility to certain toxins.

He also suggested that the disturbance of metabolism which results from vitamin deficiency may give rise to the formation of toxins in the body: this may be the cause of the toxic manifestations which are seen in beriberi.

In beriberi a toxin is at work, but there is a difference of opinion as to whether the poison is ingested or formed by bacterial agency in the intestine or produced by disordered metabolism resulting from avitaminosis. The nature of the toxin does not matter much provided that we recognise the prime importance of a sufficiency of vitamin-B in preventing beriberi.

The newer knowledge of nutrition is regarded by Col. McCarrison as the greatest advance in medical science since the days of Lister and will do for medicine what asepsis has done for surgery.

Colonel McCarrison dealt largely with avian beriberi of pigeons. True beriberi with cardiac enlargement and degeneration, neuritis and oedema, have been produced under experimental conditions in pigeons. It differs from polyneuritis columbarum (rice disease) in the enlargement and degeneration of the heart which accompany the true beriberi state. It is due to an insufficiency in the food of the anti-neuritic fraction of vitamin-B, but not to a complete want of this vitamin. Complete deprivation of vitamin-B causes polyneuritis; it rarely causes true beriberi. Beriberi columbarum is not due to toxic substances contained in deteriorated rice. Results of feeding experiments with diets (a) containing a deficiency only of vitamin-B, and (b) with diets entirely deprived of this vitamin, are entirely different.

Dr. J. P. Bose contributed a preliminary note on the inter-relationship of some of the endocrine glands

* By Lieut.-Col. J. W. D. Megaw, I.M.S.

with sugar metabolism. The work done by Dr. Bose on this subject at the suggestion of Col. Acton, and especially that with reference to the response given to insulin by rabbits of different colours has already been published; he finds that Himalayan white rabbits are the least susceptible to insulin, while the brown Belgian hares are most susceptible. Further, the response in the blood sugar fall to injections of insulin is correlated with adrenal activity. The action of the thyroid gland in connection with these differences in response to insulin was also studied, and interesting results were obtained.

Major S. S. Sokhey, I.M.S., followed with a paper on the basal metabolic rate for Indians, in which he showed how the figures obtained compare with those for Europeans. Col. McCarrison then read a paper on the effect of manganese on growth. He showed that small quantities of manganese, such as are normally present in whole wheat, cause an increased rate of growth when added to synthetic diets which are complete in all other respects. Large amounts of manganese are inimical to growth. White flour and polished rice are deficient in manganese, and in this defect may be found one of the reasons why they do not constitute satisfactory articles of diet.

Another interesting contribution by Colonel McCarrison was a paper on the relative nutritional values of the different racial diets in India. It was shown that rats fed on diets which imitate those of certain races of India showed great variations in their rate of growth. Judging by this method of biological assay, the best Indian dietary is that of the Sikhs; next, in order, come the diets of Pathans, Mahrattas, Goorkhas, Kanarese, Bengalis, and Madrassis; the last named being the worst of all. The various factors which were shown to be important were the available proteins, mineral elements, and vitamins. An association was believed to exist between the distribution of such diseases as leprosy and the nutritive value of the diets used in the various localities of India.

The next paper by Colonel McCarrison was on the effects of faulty food deficient in vitamins on the gastro-intestinal tract. It was shown that the evil results of vitamin deficiency were (i) degenerated changes in the mucous membrane, sometimes amounting to ulceration; (ii) defective digestion and assimilation; (iii) failure of the neuro-muscular control of the bowel; (iv) loss of the lymphoid elements; (v) new growth formation in the stomach, and (vi) increased susceptibility to infection by bacteria and protozoa, e.g., *Entamoeba histolytica*. The clinical manifestations of vitamin deficiency are gastritis, catarrh, dyspepsia, diarrhoea, dysentery, constipation, and gastro-intestinal stasis.

The experimental production and prevention of stone in the bladder was the subject of another paper read by Colonel McCarrison. The author had repeated and extended the experiments of Japanese workers, who were the pioneers in this line of work. The most important and remarkable finding was that the addition of fresh milk to the stone-producing dietaries prevented the formation of stone. If, as may be hoped, it is possible to prevent stone formation in man by the use of fresh milk, a very valuable addition to our knowledge is contained in this discovery by Colonel McCarrison.

The stone in the bladder which was produced in rats had the usual sequelae, cystitis, dilatation of the ureters, pyelitis, etc.

A paper on the vitamin content of whole rice was next read by Colonel McCarrison, who showed that whole rice is poor in vitamins, and that this poverty is accentuated by parboiling, milling, polishing, and washing. He believes that the frequent occurrence of beriberi among rice-eating peoples is due to the fundamental poverty of the rice grain in vitamins.

New growths in the stomach of deficiently fed rats were then described by Colonel McCarrison. These

were of a papillomatous character, and showed no definite evidences of malignancy. One of the most interesting of Colonel McCarrison's papers was on beriberi columbarum. It is well known that polyneuritis columbarum is usually regarded as being the same disease as beriberi, but as the cardiac changes are totally different in the two diseases, there is little justification for the assumption that the diseases are the same. Colonel McCarrison has now produced a disease in pigeons which has much more right to the name beriberi than the rice disease of the earlier experimenters.

Major Clive Newcomb, I.M.S., in a joint paper with Dr. G. Sankaran of Madras discussed the question of iodine metabolism in the body. They find that when small doses of potassium iodine are given, about 40 per cent. is excreted within twenty-four hours, and 20 per cent. more subsequently.

Dr. B. C. P. Jansen and Dr. W. F. Donath of Java dealt with the prophylaxis and cure of beriberi by vitamin preparations. They advocated the supply of vitamins as part of the diet, instead of buying sources of vitamins separately. In the case of rice they made an exception, as they found that unpolished rice does not keep well, and therefore it is necessary to use polished rice plus an extract of rice polishings. They have prepared an extract of vitamin-B which is very cheap and at the same time pleasant to take.

Colonel McCarrison then read two papers on goitre. In the first he dealt with the lymph-adenoid type of goitre which he regards as a hypertrophic reaction of an insufficient organ. In this there is a preponderance of lymphatic aggregates, and atrophy of the parenchyma. It can be produced experimentally by feeding an animal on a deficient diet and is due to deficiency of vitamin-B. It has no relationship to the iodine content of the diet. The second paper dealt with the endemic goitre of the Himalayas. This is a chronic hypertrophic condition associated with unhygienic conditions. The cause is believed to be the bacterial contamination of the water supply, but iodine deficiency in the intake is a contributory factor, though not the essential cause of the disease.

Major Clive Newcomb discussed the reason for the fondness of wild animals for 'salt-licks': he could find no evidence that the animals needed sodium chloride, calcium, or iodine. The reason for the animals going to the salt-licks needed further investigation.

Lieut.-Col. J. W. D. Megaw, C.I.E., I.M.S., then read a paper on epidemic dropsy and its relationship to the beriberi problem. The clinical manifestations and epidemiology of the two diseases were shown to resemble each other so closely that it is difficult to regard them as two separate diseases. He inclined to the view that epidemic dropsy is one of the diseases which belong to the beriberi group, which probably includes a number of distinct entities. He regards true beriberi as being due to an intoxication or a toxic infection, while the dry form of beriberi which is not associated with cardiac excitation may be caused by deficiency of vitamin-B.

He complained of the tendency on the part of writers on the subject to rest content with giving the name beriberi to the cases of disease which they describe, instead of stating clearly the clinical manifestations which are found. The name beriberi may be applied to different diseases, caused by unrelated agencies. For the practical control of the diseases of the beriberi group he advocated attention not merely to the nutritional qualities of the diet, but also to the question of poisons which may be produced in rice under unfavourable conditions of storage.

A very interesting discussion followed the reading of this paper, in which Dr. Victor Heiser of the Rockefeller Foundation, Colonel Vedder from Manila,

Dr. Bentley, Colonel Sprawson, I.M.S., Dr. Chuni Lal Bose, Major Jolly, I.M.S., and Colonel Gloster, I.M.S., took part. Several of the speakers agreed that further study of beriberi was needed, and that the vitamin-B deficiency view did not explain everything. The nature of the chief criticisms which were made appears from the reply by Colonel Megaw, who apologised for the shortcomings of his paper, owing to the impossibility of covering so wide a subject in the limited time at his disposal.

Replying to Colonel Vedder, who suggested that epidemic dropsy might be closely related to famine oedema, he pointed out that in the latter disease there is bradycardia and polyuria; also that the obvious defects in the diet of the victims of famine oedema made the occurrence of such a disease inevitable, whereas no obvious defect can be found in the diet of persons who suffer from epidemic dropsy. Colonel Vedder also pointed out that a similar toxin had been detected in the rice which had been eaten by persons not suffering from epidemic dropsy. Colonel Megaw replied that Colonel Acton and others had claimed to have isolated this toxin; but even if their findings were not accepted, it became a question of a hypothetical poison which fitted in with the observed facts, against a hypothetical avitaminosis which did not fit in with the known facts, and was extremely unlikely to occur in the diets of the persons concerned. Colonel Vedder asked whether treatment by food extracts had been tried: the reply was that striking success had been obtained by a rice-free diet containing abundant available proteins, fresh milk being the most suitable diet of all.

Dr. Sahaha had given reasons for believing that epidemic dropsy was communicable from person to person, but Colonel Megaw emphasized that the fact that hundreds of patients had gone to health resorts outside the epidemic area, yet none of them had conveyed the disease to any of the people in these places. Dr. Bentley asked for a detailed account of the diets of the victims for a long period prior to the onset of the disease. Colonel Megaw replied that a detailed analysis of the actual diets which had caused the disease was out of the question, as it was impossible to predict the occurrence of epidemic dropsy; but he said that no difference could be found between the diets of the patients and those of their neighbours. He also asked whether it was conceivable that explosive outbreaks of such a disease could be explained on the avitaminosis theory, especially as many of the persons who were affected had been living on an exceptionally satisfactory diets.

Colonel Sprawson referred to cases in which there was no rice in the diet, but only wheat flour which had been stored. The reply to this was that it is quite conceivable that poisons may also be found in stored wheat flour, but if this occurred it must be very rare; also the possibility of adulteration of wheat flour by rice flour had to be considered. In any case, storage of all food grains and flours ought to be attended to with great care, and far too little attention had been paid to this subject in the past. Colonel Kelsall believed that epidemic dropsy differed essentially from beriberi in being an explosive disease, and also in certain clinical respects, but Colonel Megaw pointed out that epidemic dropsy was not always explosive, while beriberi sometimes was explosive. Some outbreaks of epidemic dropsy differed strikingly from some outbreaks of beriberi, but when all the outbreaks of both diseases were investigated it was impossible to draw the line between the two diseases.

Major Jolly enquired whether the mixing of powdered lime with rice had been found to be effective in preventing the disease. Major Stott referred to this point in his remarks, and related how the prisoners in the Calcutta jails had escaped during the Calcutta outbreak of 1909. Their immunity had been attributed to the use of lime, and to the special care

in the storage of the rice. Dr. Chuni Lal Bose, in criticising the suggestion that poisoned mustard oil might be responsible for epidemic dropsy, produced evidence of the occurrence of the disease among persons who did not use mustard oil. Colonel Megaw accepted this criticism and pointed out that he himself did not believe that mustard oil was responsible, but merely suggested that this was one of the food-stuffs which required attention. Colonel Gloster asked for evidence that any samples of rice could be responsible for epidemic dropsy and beriberi. Colonel Megaw replied that if a sample of rice were responsible, it would usually be impossible to obtain it, as the offending rice would almost always have been consumed by the time that the symptoms appeared and before suspicion was aroused. The evidence pointed to the occurrence of the poison in sharply circumscribed samples of rice, rather than as a widely disseminated poison in the whole supply in a store house.

He expressed regret that neither Colonel Vedder nor Colonel McCarrison had been able to supply any criterion by which it would be possible to place epidemic dropsy in a disease group distinct from the main beriberi group, and he invited them to examine the data on epidemic dropsy which had been collected by his assistants and himself. In conclusion he asked for a broad consideration of the whole epidemic dropsy and beriberi problem as well as for a close examination of details: he believed that the truth might be arrived at by making a wide and comprehensive survey of the question.

PHARMACOLOGY : DRUG ADDICTION.

In this Section, Major Chopra read a very interesting paper summarising his research work of the past six years on Indian indigenous drugs.

"A large number of medicinal plants grow in India and during the last six years a systematic study of these has been undertaken. Firstly, the drugs of known value which are recognised by the British and other Pharmacopœias are being investigated, in order to see whether the standard of active principles of those growing in India is equal to those used in the Pharmacopœias. The allied species of these plants which grow in this country are also being examined in order to see if they can be used in therapeutics in place of the official drugs. A number of drugs belonging to this class have been examined. *Artemisia brevifolia* Wall and *A. maritima* (Linn) grow abundantly in the Northern Himalayas and yield excellent santonin. Good quality of *Digitalis purpurea* grows in Kashmir and in Mungpoo near Darjeeling. *Psychotria ipecacuanha* can be grown in certain parts of the Himalayas, and gives a good yield of emetine. Valerian, hyoscyamus, belladonna, podophyllum, colocynth, colchicum, juniper and many species of aconite grow in different parts of India and are of excellent quality.

Secondly, research has been directed towards the investigation of well known remedies that are used in the indigenous systems of medicine in vogue in this country. These remedies are being gradually analysed, their active principles isolated and their pharmacological actions are being worked out. We are also trying them clinically in order to see whether the claims made regarding their efficacy can be proved or disproved. We have worked out a number of such drugs. *Bærrhavia diffusa* (Punarnava) is a good diuretic; *Vitex peduncularis* and *Berberis aristata* are useless in malaria. *Butea-frondosa* (Polas) and *Serrutula anthelmintica* (Somraj) are good anthelmintics; *Psoralea corylifolia* (Buckchi or Babchi) have given good results in the treatment of leucoderma; *Saussurea lappa* (Kuth root) is a very effective antispasmodic and is an excellent remedy for certain types of asthma and persistent hiccough; the alkaloid conessine from *Holarrhena anti-dysenterica* (Kurchi) promises to be of use in amoebic dysentery; *Sida cardifolia* (Barela)

possesses a very potent alkaloid whose action resembles that of ephedrine."

Major Chopra then read a paper by himself and his colleagues on the pharmacological action of the cinchona alkaloids on the heart and uterus; and this was followed by a joint paper by Major Chopra and Dr. K. S. Grewal on the opium habit in India. This last paper aroused considerable interest.

Stating that the opium habit was of comparatively recent origin, and that it appeared to have come gradually into being after the poppy was introduced into the country by the Mohammedans, Major Chopra said: The policy of the Indian Government in respect of the domestic consumption of opium in India has been criticised. The Indian Government have asserted that it is a matter purely for the British and Indian Governments, and not an international question. The questions we have to consider in answering these criticisms are: Is opium addiction very common in India; is the habit spreading, and is the consumption so great as to be a menace to the health and the morality of the people in general?

Although no statistical data regarding the number of addicts are available, a careful study of the question shows that though the opium habit may have been very prevalent in the 17th and 18th centuries, it never could have been so widely spread and abused as it has been in other Eastern countries. The ravages which it is said to have produced in countries like China and elsewhere have no parallel so far as India is concerned.

Sir William Robert in his minute in the Opium Commission Report says: Taking India as a whole it may be said that a small minority even of the adult male population take opium habitually. That was 32 years ago. We have carefully gone into the matter and have collected statistics from the excise records and from work in the field to gauge the extent of opium consumption in the country at the present time.

We have been forcibly struck by the fact that the opium habit is not nearly so common in India now as might be imagined from some of the recent publications by authors who have interested themselves in this question. Although opium is still administered extensively to infants in many parts, the habit is not widely disseminated among the adult population throughout India. Its incidence among various peoples is very irregular, and although there are certain areas and certain classes of population which are badly affected these form a very small minority.

Our investigations in the Punjab show that in the central districts of that province, which are populated chiefly by Sikhs, the consumption of opium recorded is one of the highest in the whole of India, with the exception perhaps of Assam and Calcutta. The percentage of addicts is about 0.1 per cent. of the total population. In most of the other districts of that province the consumption of opium is up to the standard laid down by the League of Nations as being necessary for medical and scientific purposes, and the number of addicts in these areas is not even 1 in 20,000 to 1 in 25,000.

Referring to the question of doping of infants and children, Major Chopra said: "From a rough general survey of most parts of India that we have made it appears that this custom chiefly prevails at present among the population of areas round large industrial centres, but on the whole the practice is becoming less and less common in the rural areas, and has entirely disappeared in many parts where it existed before. Basing our opinion on our investigations in the Punjab again, we have also been impressed with the fact that the opium habit among the aged is not nearly so prevalent now as it was two or three decades ago.

We have, therefore, come to the conclusion that the opium habit in India is not very common, and is

certainly not spreading. In fact our investigations in the field go to show that during the last fifteen years the addiction has considerably decreased. This is also obvious from the fact that the quantity of excise opium issued for consumption in British India, including Burma, during 1925-26 was roughly 600,748 lbs. as compared with 855,721 lbs. in 1919-20, and 1,031,227 lbs. in 1911-12. The decrease is much more marked in the last few years than in the previous decade.

The factors which have been chiefly instrumental in reducing the consumption of opium in India are the decrease in its production and increase in its price. Some people have advocated a further increase in price so as to make its use prohibitive from the nature of its costliness. As has been rightly pointed out this will only lead to increased smuggling from the Indian States, Persia and Afghanistan, and defeat its own object.

The next question is, what is the effect of the opium habit on the addict? This can only be answered by patient work in the field and observations on a large number of addicts. During the last two years we have been able to study more than 700 addicts both in towns and rural areas. From the data we have collected the Indian addicts are divisible into three main groups. Under the first group come all those persons who resort to the drug because they find it gives them relief from certain diseases or minor ailments, and as many as 30 to 40 per cent. of the addicts in our series came under this category. Though the State is doing all that is possible to increase the facilities for medical aid to the masses, the majority of the population still resort to very primitive methods of treatment and that accounts for opium being used as a household remedy. They do not realize the fact that drugs like opium are merely palliative, but have no curative value. The second group, comprising about 10 to 20 per cent., includes those people who have been working under strain and stress of life unbearable to them, and take the drug to forget their worries and anxieties.

The third group of addicts consists of those who get to taking opium for the purpose of self-gratification, and comprise about 30 to 40 per cent. of the total addicts. These people are generally well off, and start taking the drug for its stimulant action or for the comfort which it affords them. The addicts are generally between the ages of 20 and 35, and this class of addicts is on the increase, both in cities and rural areas, while the others show a decrease. Under this group are also included a large criminal class who often start taking opium under the impression that it fortifies them and enables them to bear the physical and mental strain connected with their nefarious work. Our investigations into facts show that a large percentage of this population are addicted to opium. In all these groups association with the addicts plays a very important part in starting the habit.

Proceeding to discuss the effects of opium habit on health, Major Chopra said: "The addicts who generally show no outward signs of the habit either physical or mental and who consider the habit was not doing them any harm, are those who take small doses not exceeding five grains a day. Most of the other addicts tell you that the habit is doing them harm. They say that they have not the same energy and vigour as they had before, they are unable to do hard physical work for any length of time, and are incapable of mentally concentrating their attention to do any highly intellectual work. Our own experience bears out these facts, and we find that, generally, those addicts who take more than five grains a day become both physically and mentally dull. Their output of work is not equal to that of non-eaters of opium. Small doses, would, therefore, appear to produce apparently little effect, but with larger doses there are obvious signs of deterioration of the general health of the individual.

(To be concluded in our issue for next month.)

MARCH.

THE ADVANCE OF MEDICINE AND MEDICAL EDUCATION.

THOSE of us who can look back thirty or forty years are filled with wonder at the rapid strides which have been made in medical and surgical practice during our lifetimes. Advancing knowledge has simplified many problems but it has brought fresh difficulties in its wake.

On the one hand it is now possible to teach the student how to manage cases of malaria and dysentery and syphilis with a degree of efficiency that was unheard of in our student days, and diseases like kala-azar which used to be approached with sinking of the heart are now dealt with in a spirit of justifiable optimism. On the other hand specialisation has made such advances that the general practitioner finds himself in the unpleasant position of being years behind the standards of efficiency which have been set up both in medicine and surgery. The specialist who can confine himself to a narrow sphere of activity has no difficulty in his own subject, but as far as India is concerned the real specialist is almost non-existent; it is only in the larger centres of population that there is any scope for him. At any rate the specialist is not yet of much importance in India as far as the medical relief of the masses is concerned. It is true that he plays an important part in teaching the general practitioners of the future and in this connection it is essential that he should have a due sense of proportion. He must remember that he is not training the specialists of the future, and if his instruction is based on the assumption that his pupils have nothing to learn except the subject which he teaches, the result will be confusion.

Many of the modern textbooks are seriously at fault in this respect, they are written on the assumption that all the resources of the specialist are at the disposal of their readers. Such books are not of much value to the man whose work lies in an out of the way dispensary.

Operations are described which could be performed only by a Moynihan, and even he would hesitate to operate under the conditions which usually exist in India. It is often assumed that there is one best treatment for each disease, the truth is that there may be several; that which is best in the hands of the expert might be the worst in the hands of the inexperienced surgeon who has the most primitive resources at his disposal. An example near home may make the point clear. Smith's operation for cataract has yielded results which appear to be superior to those obtained by the old-fashioned methods, but which of us

would choose Smith's operation if the only available operator were a surgeon who had only extracted a dozen cataracts? Again, if one of us were suffering from a disease of the gall-bladder or stomach for which the ideal treatment is a delicate operation such as could easily be performed by an expert, would we submit to the operation in the average Indian dispensary?

Obviously there must be two distinct lines of teaching, the one for the specialist of the future, the other for the general practitioner. The same problem exists in other countries, but it is perhaps more acute in India than in Europe and America.

In theory it sounds attractive to aim at having only one grade of practitioner but in practice there is a need for several grades. Under existing conditions we cannot expect to staff all the little dispensaries of India with men who have an elaborate and expensive training, and even if we could, such highly trained men would break their hearts in places where there is no opportunity for the exercise of their great abilities.

At least three grades of practitioners are needed, the specialist, the highly trained general practitioner, and the village doctor. Under existing conditions the specialist can only make a living in the larger centres, but much can be done by encouraging doctors to engage in limited specialisation in places where there are several medical men.

In Bombay and Calcutta there is a great opportunity for specialism, and division of labour, but even in places like these less than one per cent. of the practitioners make any pretence at specialisation so that there is little hope at present for securing a suitable division of labour in smaller places. The real problem in India is whether we are to adopt the principle of turning out large numbers of indifferently trained doctors or of aiming at a high standard of efficiency. Our view is that the interests of the people and of the profession will be best served by maintaining reasonably high standards rather than by flooding the country with poorly trained men. The policy of opening large numbers of medical schools in India should be carefully controlled. What is needed is the complete overhaul of existing institutions with a view to raising the standards of efficiency rather than to follow the ruinous policy of turning out huge numbers of medical men. Fifty years ago it was possible for any young man of good intelligence to master the existing knowledge of medical work; now that medical science has become so vast and complex we are faced with a new situation, and our system of education ought to be remodelled to meet new conditions.

Education has always been in the hands of conservatives, the educated man finds it difficult to imagine that any one can claim to be cultured if he has not pursued the same courses of instruction as were in vogue in his youthful days. Medical education has been less conservative than other branches, but it is tied to the chariot

wheels of the Universities and reforms are made with difficulty. But such obstacles can easily be exaggerated, curricula need not be adhered to in a slavish manner and if the ranks of the teachers and examiners are recruited from men who have breadth of view, neither the restrictions of Universities nor of Medical Councils will interfere with the essential reforms. It is the men who count rather than the machinery of education. But there must be intelligent co-operation between teachers and examiners. It is useless for any teacher to try to train up his students in the essentials of his subject if the examiners insist on asking questions which are intended to display their own erudition.

The medical curriculum is now so vast that it is essential that everything that is unimportant should be scrapped, but it is most disheartening to teacher and students alike if little credit is obtained for a knowledge of important matters and if it is necessary to waste time in the study of subjects which have no bearing on the student's life work.

Beyond everything else what is needed is a sense of proportion; we must keep before our eyes the work which will be done by the practitioners who are being instructed and examined, and we must remember that they have limited powers of assimilating knowledge. Our business is to put first things first, to be quite sure that the essentials have been mastered before we lead our pupils into the attractive higher flights. Speaking with experience, we assert that the existing system of medical education in India fails chiefly because it aims at impossible standards.

TROPICAL NEURASTHENIA.

THIS disease has been much discussed during the past year or two and the question arises whether it is so much more frequent in the tropics as to justify the use of the name "tropical" neurasthenia. The disease is a state of exhaustion of the nervous system, over work, and especially worry being the chief factors in causation. Physical health plays an important part, it is impossible to have a healthy nervous system in a diseased body.

It is obvious that malaria, dysentery, and other tropical diseases will lower the vitality of the nervous system and so make it more liable to exhaustion. Climate itself is a factor; the tone of all the body tissues is lowered by prolonged existence in unfavourable climatic conditions.

Wrong habits of life must be taken into account, alcohol, unsuitable diet, too much or too little exercise, enforced continence and so forth, while life in the tropics has its special dangers which may give rise to a state of conscious or unconscious dread, it has its big and little worries.

Exposure to bright sunlight in the tropics is usually accompanied by exposure to excessive heat, and it becomes difficult to determine the part which bright light plays in damaging the body.

Glare is well known as a cause of headache; probably this is brought about partly by damage to the retina, partly by overstimulation of the visual cortex. It is not likely that the direct action of light rays causes much damage to the body, unless the exposure is excessive. Many persons who live in the tropics protect themselves from the sun to such an extent that they suffer from insufficient light rather than from excess.

Wrong habits of life play their part in causing lowered bodily vitality; alcohol is usually regarded as the friend of the white man in the tropics, too often it is one of the friends from whom we should pray to be saved. Diet is important, partly because it is often difficult to obtain a nutritious fare, partly because animal proteins are often eaten in excess, but the chief error of diet in the tropics is probably the eating of small quantities of tasty food to the exclusion of the more bulky articles which leave a solid residue. Intestinal stasis and intoxication result from this kind of diet. Exercise may be overdone or on the other hand it may be neglected. Some medical men attach importance to the lack of outlet for the sexual impulses, and it is likely that enforced bachelorhood is harmful, though by no means so harmful as unrestrained sexual intercourse. Suggestion plays an important part; life in the tropics is sometimes gay and care free, but on the other hand it is often filled to overflowing with worries and troubles and there are far greater opportunities for introspection than is the case in Europe.

Endocrine insufficiency is emphasised by some, but this is probably rather an after effect of lowered vitality than a cause. All the same it may help in the establishing of a vicious circle and is worthy of attention. Apart from climatic conditions and disease there is probably no factor inherent to the tropics which is of special importance in the causation of neurasthenia and it is doubtful whether we are justified in creating a special clinical entity under the name tropical neurasthenia. Some German writers have described a mental condition which they call "furor

Corrigendum.

Omitted from page 74, February 1928.

Fig. 1.—Comparator devised by the author.

tropicus" but it is not likely that this would be accepted in a court of law as an excuse for murder or manslaughter.

Each case of neurasthenia in the tropics should be judged on its own merits, and it is likely that in most cases a reformation in the habits of life would bring about a cure just as certainly as in colder countries. When the conditions which give rise to the disease cannot be mended they should be ended by sending the patient on leave to a cheerful and healthy locality, preferably to Europe.

SPECIAL ARTICLE.

GYNÆCOLOGY AND OBSTETRICS, 1927. A PRACTICAL DIGEST.

By V. B. GREEN-ARMYTAGE M.D., F.R.C.P.
(*London*),

LIEUT.-COL., I.M.S.,
*Professor of Gynæcology and Obstetrics, Medical
College, Calcutta, and Surgeon to the Eden
Hospital.*

THE past year has not been remarkable for any very important new work in the field of gynæcology, but workers throughout the world by means of "follow-up" systems have been attempting to estimate the end results of operations, and to co-operate as regards treatment.

For instance, Lynch has found that backache was a complaint in 49 per cent. of 1,041 women who were operated upon for lesions of the pelvic organs; in 77 per cent. this pre-operative symptom remained cured. He is of the opinion that backache is chiefly due to pelvic congestion, whereas Schroeder considers that it is due most often to a chronic lymphangitis or to a contraction of the utero-sacral ligaments, or an endocervicitis with erosion.

Fulkerson analysed 1,039 cases of endocervicitis with erosion and discovered that this condition existed in 33 per cent. of all gynæcological patients. Traumatism of labour and abortions appear to be the chief factors, and accounted for 80 per cent. As regards the treatment of erosion and endocervicitis, provided there is no adnexal disease, the electric cautery method of treatment gives by far the best results, especially if further conception is desired.

Sterility, abortions, and difficult labour are frequently reported or complained of after high amputation of the cervix.

Malpositions.

Bullard reports on a study of the results of 361 operations for prolapsus uteri. The Watkins operation was performed on 77 patients with successful results in 96 per cent. and complete failure in 4 per cent. The Mayo operation was performed in 50 cases with a 94 per cent. success. Vaginal hysterectomy was performed for prolapse in 74 cases, with complete success in 78

per cent. There were no deaths and the general consensus of opinion would appear to be that the interposition operation produces the least shock, though when combined with an extensive colporrhaphy, there is the danger of sloughing and *B. coli* infection.

The most striking point about this study and the one most applicable to India, is that 95 per cent. of cases of uterine prolapse can be cured by vaginal plastic surgery, for prolapsus uteri is a hernia through the pelvic floor, and under no circumstances should it be treated by abdominal ventrofixation.

Danforth and Galloway investigated the frequency of retroversion of the uterus in a series of 1,000 private patients. They found that nearly 20 per cent. had this condition during early pregnancy, and the puerperium.

It is necessary to emphasise the fact that over 20 per cent. of women carry their uteri in a retroverted position and that advantage should not be taken of this fact for pelvic engineering.

Malignancy.

The clinical classification of cancer of the cervix is still the best way of making a prognosis. A great number of reports from all over the world have been received which indicate that we are unable to attach any value to the predominating cell type of cancer as a prognostic index.

The question as to whether to operate or not to operate in cases of cancer of the cervix, still agitates the gynæcological world. For instance, Doderlein sums up his experience in 2,300 cases of carcinoma and concludes that radiological treatment is superior to the operative, as it is successful in curing a small portion of even inoperable cases.

Reguad states that radium treatment effects a cure in 15 per cent. to 20 per cent. of cancer of the cervix, regardless of the stage of development of the cancer; in inoperable cases the incidence of cure is from 5 to 10 per cent. while in the operable cases it is from 30 per cent. to 40 per cent. But Heyman of Copenhagen sounds a note of warning and states that the deeper cancer cells are not affected by radium rays, and that these cells proliferate and reduce the chances of success. The writer himself has seen 31 cases with deep parametrial or bony invasion from one to three years after treatment by radium at RANCHI. Ward and Farrar in a critical review and analysis of carcinoma of the cervix, conclude that radium alone is preferable to surgery.

Such being the radiological aspect of the case, it behoves us to look at the other side of the picture in the hands of Mr. Victor Bonny whose superb dexterity and technique is world-famous. He has performed the Wertheim operation for cancer of the cervix in 214 of 340 unselected cases: 34 of the 214 patients died from the operation, 82 died from recurrence, and 85—that is 39.7 per cent.—were free from recurrence after five years. The writer is of the opinion that

operation is the method of choice in properly selected cases, for in spite of the inspired statistics and ambitions of the radiologists the death rate remains without change.

The whole problem of cancer is (1) of prevention, and (2) of early recognition, and until the public, and especially women, recognise and appreciate that cancer in its early stage is operatively curable, the mortality and disability from this disease will continue. It is suggested that just as people go to their dental surgeon for overhaul once in six months, women should after the age of 35 at regular intervals be examined as regards their mammary and genital organs by an expert.

Findlay in an excellent paper on pre-cancerous lesions advocates vigorous education of the laity. He considers a lesion as pre-cancerous when the epithelial cells are enlarged, irregular in size, with hyper-chromatic nuclei and indistinct border outline.

Ectopic Pregnancy.

This condition is frequently missed and much unnecessary suffering results from lack of courage on the part of the medical attendant. The writer wishes to call attention to referred pain in one or other shoulder as a particularly useful symptom where intra-abdominal hæmorrhage has occurred, and the value of puncture of the posterior vaginal wall with a Record syringe needle. In cases of doubt where an urgent diagnosis lies between hæmorrhage and inflammation, repeated taking of the leucocyte count, blood pressure, and hæmoglobin percentage may make diagnosis certain.

A profuse hæmatoma ovarii is the only other condition which can give a similar clinical picture. The treatment is the same in both—laparotomy.

Puerperal Infection.

The recent work of Hofbauer of the Johns Hopkins University on the cellular defence in the parametrium is of great significance.

Metchnikoff pointed out years ago that the polynuclear cells of the blood ingested living bacteria, while the mononuclear cells ingest cell debris, and to a more limited degree the bacteria. He further observed that the mononuclear cells had their origin from fixed tissues of mesoblastic origin. Applying these observations on phagocytosis to the infected uterus, we have long known of a cellular defence in the decidua, the so-called granulation zone composed of polynuclear leucocytes.

In the acute stages of infection the polynuclear cells greatly outnumber the mononuclear cells, whereas in the later stage the mononuclear outnumber the polynuclear. These facts have long been known, but it remained for Hofbauer to demonstrate specific types of cells in the cervix, in the lower uterine segment, and more particularly in the parametrium at the base of the broad ligaments. These cells he classifies as

monocytes and clasmatocytes. They are present as early as the third month of normal pregnancy and increase in number as pregnancy advances.

In the event of prolonged labour or infection the increase in these cell elements is very great. Hofbauer believes that these cells originate from small oval cells which are grouped around the small blood vessels. He has clearly demonstrated that the monocytes and clasmatocytes are phagocytes and belong to the order of fixed cells of the reticulo-endothelial system. They obey the same laws as leucocytes and take up not only bacteria, but also fragments of cells and tissues.

That these cells are of immense importance in the biological defence of the body against puerperal infection there can be no doubt. The researches of Hofbauer have been confirmed by many other workers on the subject of bacteriophages and macrophages, but the only question that remains to be solved is the nature of the stimulant which gives rise to the presence and increasing numbers of these cells.

Many biochemists consider that it is a foreign protein, for it has been observed that the process of resolution of inflammatory deposit in the parametrium and pelvic peritoneum is greatly accelerated or assisted by the injection of such non-specific proteins as milk (which is injected intramuscularly in doses of 5 to 10 c.c. twice a week).

The reaction following these injections is an index of the stimulation of these clasmatocytes and monocytes of the reticulo-endothelial system; but Hofbauer doubts this explanation because the maximum activity of chorionic imporation through the blood-stream is in the early months of pregnancy, whereas the cellular reaction in the parametrium is at its height at the end of pregnancy. He believes that the hormone X, or whatever substance produces the well-known changes in the various organs of the pregnant woman, causes the parametrial phenomena, and that the invasion by bacteria of the parametrium supplies the impetus for the added increase which is seen to such a marked degree in the event of infection. It is possible that such chemical substances as iodine, mercurochrome, quinine, etc., injected into the blood, have their occasional success indirectly by stimulating bacteriophages and macrophages.

Induction of Labour.

In former reviews during the last few years, the writer has stressed the importance of forestalling post-maturity when the size of the baby is obviously large. The various methods of induction, whether at term or before term, have been indicated such as the castor oil-quinine-pituitary (minims 3) technique, the stomach tube, the balloon or bougie method. During the last year, however, Hofbauer and Hoerner of the Johns Hopkins University have published a very interesting paper on the nasal application of pituitary extract for the induction of labour. In 56 cases for conditions such as toxæmia, post-maturity, severe pyelitis and hydramnios, labour

was induced successfully in every instance. Nine failures occurred out of 24 cases where the external os was tightly closed before normal full term.

Technique.

Under direct vision with the aid of a nasal speculum, the nose is gently cleaned of any discharge or crusting. A small pledget of wool is then prepared and moistened with 20 minims of pituitary extract. This is placed snugly and firmly under the anterior end of the inferior turbinate. Within one to five minutes after the application vigorous uterine contractions will occur, and if the original contraction lasts more than four minutes the pledget is withdrawn. In the majority of cases rhythmic labour contractions alternating with periods of relaxation are the normal outcome. Should the pain tend to wear off and labour not to set in within two hours, the first pledget is withdrawn and another put in. In the majority of cases one to three applications of pituitrin on wool are required; in a very few cases as many as five doses are necessary. At the end of one hour, or at most two hours, the pledget is withdrawn and a fresh one applied to the opposite nostril for a similar period of time. Any abnormal condition of the patient such as acute coryza or chronic nasal catarrh, mitigates against absorption of the drug.

The authors' conclusions are that this method is a safe one for the induction of labour or for accelerating labour already in progress. In their series all the babies were born alive, and they conclude by stating that the possibility of withdrawing the drug and thus preventing its further absorption as soon as the uterus passes into tetanic contraction renders the nasal application of pituitary extract the safest method yet available for obstetric purposes.

They emphasise two things: (1) that in any method of inducing labour by means of pituitary extract, the administration of the second dose must not be before the effect of the first dose has worn off; (2) after cleansing the nose, the pledget of wool soaked in pituitrin must be firmly applied to the inferior turbinate bone.

The writer since reading this communication has used it on 7 occasions with complete success.

The "Failed Forceps" case has come into a good deal of prominence during the year, and several papers have demonstrated that these cases are more common than they should be, and indicate that the fundamental principles of midwifery are far from being understood by the general practitioner.

Farquhar Murray reported 52 cases admitted to hospital, the majority of these were cases of contracted pelvis or occipito-posterior position. Despite the fact that expert attention was given after arrival in hospital, it is melancholy to think that out of the 52, eight mothers died and 27 babies were still-born and four more died within a few days of delivery. Such facts forcibly demonstrate that the public is not yet educated to

the benefits of antenatal care and of primary hospital treatment, for it is safe to say that probably all these lives would have been saved had they been attended to in the first place by men or nurses who were efficiently trained.

Shannon has given an equally damning report from Glasgow. If these conditions are possible in the United Kingdom despite preaching and teaching, it makes for greater pessimism in India where countless lives every year are sacrificed through neglect, prejudice and ignorance.

The writer wishes to emphasise again the dire importance of all obstetricians in hospitals in India learning and practising the low Cæsarean section of De Lee. This is an operation of comparative ease, causes very little shock or bleeding, and can be done in India more often than in any other country in the world, for here we see all the contracted pelvis cases late and usually after labour has lasted some hours, when the membranes have ruptured and many examinations have been made. But despite all these deterrents, if the baby is alive the operation can be done with every chance of saving mother and child.

The writer has done a great many since 1925, when he saw De Lee do it in Chicago, and has not lost a mother or child as yet; he looks upon it as an ideal operation for India. When the patient is in labour, it is very easy, for the lower uterine segment is immediately under the parietal incision. The lower segment is always incised transversely, and if infection is certain then a low suprapubic drain is left in. It is remarkable how even the worst cases do well, and what *bien-être* these patients experience as compared with the classical operation. The writer has been urging this method since 1925 (vide *Indian Medical Gazette*, February 1926) and it is consoling to find that even so conservative a place as the Rotunda is now advocating this method in all late cases (vide *British Medical Journal*, November 1927). Surely now the women's hospitals of India will follow suit.

During the last seven years 69 Cæsarean sections have been performed in the Eden Hospital, and 18 in private practice for the following conditions:—

Pelvic Contractions.

Small round pelvis	.. 12
Contracted outlet	.. 11
Flat pelvis	.. 9
Osteomalacia	.. 12
Robert's pelvis	.. 2
Kyphoscoliosis	.. 1
Tuberculosis of the hip	.. 1

Malpresentations.

Impacted twins	.. 1
Breech and hydrocephalus	.. 1

Other Conditions.

Stenosis of cervix or vagina	.. 3
Carcinoma of cervix	.. 1
Eclampsia	.. 8

	Without pelvic abnormality ..	4
	With pelvic abnormality ..	4
Central placenta prævia ..	2	
Adhesions following a former Cæsarean ..	2	
Elderly primiparae ..	7	
Pregnancy with fibroid ..	2	
Heart disease ..	2	
Post-maturity (big baby) ..	35	
Pulmonary tuberculosis ..	3	
Pregnancy subsequent to Fothergill operation for prolapse ..	2	
Total ..	87 cases	

If such have been the average incidence and indications for our Cæsarean section during seven years, it will be recognised how all-important it is that the modern technique of the low Cæsarean operation should be mastered by those hospitals in India which are staffed entirely by women.

Considering the fact that during the last two years four cases have been seen of rupture of the scar of a previous Cæsarean section done in another hospital, it will not be out of place to record that Eardley Holland has reported that the incidence of secondary rupture is 4 per cent. Such a rupture may be due to (1) non-apposition of the uterine muscle, with the result that fibrous tissue replaces muscle tissue; (2) infection of the scar, with degeneration of the uterine muscle fibres during the puerperium; (3) the situation of the placenta on the anterior wall of the uterus at the time of the previous operation; (4) the employment of catgut or silk as suture material.

It is interesting to note that in the four cases which were admitted *in extremis* with rupture of the previous Cæsarean scar, that in two the abdominal scar showed obvious signs of having suppurated, and in all the history obtained from the hospital and surgeons concerned was that the suture material used for the uterus was entirely catgut.

In 17 years at the Eden Hospital the writer has never seen or heard of one of our cases ever rupturing, although the number of cases of patients coming to hospital for second and even third Cæsarean section has been very large. The writer attributes this freedom from secondary disaster entirely to the fact that it has been the rule and procedure for over twenty years to use interrupted silkworm-gut through the peritoneum and uterine muscle, but not of course allowing it to traverse the endometrium. The silkworm-gut and the peritoneal scar are finally closed and hidden by a continuous Lembert catgut stitch.

Glucose.

Titus and Dodds have recently stressed the importance of intravenous glucose in many conditions, particularly after severe operations as a preventative of shock, distension, nausea and acidosis. It is of great service in obstetric shock and after Cæsarean section. The authors em-

phasise the fact that anomalous symptoms only occur where there has been faulty technique in the preparation of the solution, and that whereas a 25 per cent. solution is the best to employ, a 10 per cent. solution is the minimum strength which it is wise to use.

The solution can be made from Merck's chemically pure glucose, or better still from ampoules of the drug ready prepared by Martindale. The diluent should be freshly prepared with double distilled water and *not* saline. When ready for use there should be no flakes or particles in the solution. Titus is of the opinion that 200 c.c. of a 25 per cent. solution acts more efficiently and rapidly than a 1,000 c.c. of a 10 per cent. solution. The intravenous injection must be given very slowly, i.e., not more rapidly than 4 c.c. per minute. Insulin may be administered at the same time, and as a general rule 10 to 15 units at the beginning and the same quantity at the end of the intravenous are added.

At the Sixth British Congress of Gynæcologists last year a very spirited discussion arose as to whether operation was the best method of dealing with the *acute pelvis of gonorrhœa*. It was advocated by some that early operation cut short the disease, and that a salpingostomy was a safe and good procedure, in that pregnancy was possible afterwards. My own experience does not bear this out; the necessary drainage, always above and occasionally below, makes convalescence painful and slow, and seeing that many gonococcal infections are mixed with infection due to other organisms, one doubts whether one is justified in running the risk of spreading an infection to the upper abdomen.

Expectant treatment gives uniformly good results in the average case, and there can be few practitioners who have not seen complete resolution after severe pelvic gonorrhœal infections. If in such a case sterility follows, it is more than probable that although nothing is palpable, there may exist only filmy adhesions at the fimbriated end of the tube (the phimotic tube) or that there are mechanical kinks in the length of the tube.

Such conditions can be dealt with at a suitable date by laparotomy, and confirmation as to the patency of the tubes can be demonstrated by insufflation during or before laparotomy. Most authorities at the Congress were in favour of conservatism, that is dealing with the tubovarian condition (if it existed with symptoms) after the subsidence of the acute stage, when the organisms had died and operation was safe.

Solomons has communicated an interesting paper on the subject of *sterility* where the husband is normal and there is a negative Rubin test. He advocates in every such case that the abdomen should be opened and a variety of plastic operations performed on the tube. He divides his cases into three classes:—

(1) Where the adhesions are at the fimbriated end of the tube only. In such the adhesions are

freed and a piece of No. 2 catgut is placed in the lumen of the tube. In 72 cases where this was done, he reports 32 pregnancies.

(2) Where the end of the tube is resected and catgut is inserted as before. Results, 6 pregnancies in 25 patients.

(3) Where the disease is demonstrated at the time of operation to be at the isthmus of the tube. In these the blocked area is resected, and then after bisecting the uterus, a piece of catgut is threaded through the uterine ostium to emerge at the cornu and thence is passed into that portion of the tube that is patent. Results, 15 operations, one uterine pregnancy and two tubal.

These results are too optimistic to be unreservedly accepted. It is difficult to see why the Dublin patients do better than any others; few authorities will agree with his results and many might doubt the accuracy of the original diagnosis.

Placenta prævia has come in for a good deal of discussion during the last year, for there is a growing dissatisfaction with the results of the best clinics. For instance in Edinburgh, during ten years the maternal mortality was 9 per cent. and the foetal 64 per cent; in Glasgow the mortalities were 11 per cent. and 71 per cent. respectively; in New York the mortalities were 7 per cent. and 47 per cent. Such being the statistics it is no wonder that obstetricians are turning away from the older methods, and attempting to reduce the mortalities by newer means. Cæsarean section is the method which is now most advocated but it must be understood that this is not a routine measure; each case must be considered on its merits, but if the child is alive and viable this is an added reason for Cæsarean section.

Watson states that it cannot be too strongly emphasised to the profession that success in dealing with a case of *placenta prævia* depends upon

(1) The immediate hospitalization of the patient at the first hæmorrhage.

(2) The examination of the patient only after the most careful preparation, and when everything is ready and at hand for treatment.

(3) Transfusion of cases before or after treatment is carried out.

If we saw all cases before any treatment was carried out, such as packing or "bagging," a larger number would be found in the Cæsarean class, and as a result there would be an improvement in the respective mortalities. A very large number would perhaps require no other treatment than rupture of the membranes.

Packing, with or without version, is a procedure which greatly increases the mortality, but yet it is the only method at the disposal of the general practitioner far from efficient hospital aid.

Practically all authorities are agreed that the best treatment in a primipara, or if there be a central placenta, or any contraction of the pelvis

is Cæsarean section. Statistics indicate that a quarter of the cases die of antepartum hæmorrhage, a half die of postpartum hæmorrhage, and a quarter of die of sepsis.

It is not sufficiently known that postpartum hæmorrhage is one of the most deadly features of *placenta prævia*. Therefore every means should be taken to forestall such an occurrence. Blood transfusion is the best means; some advocate in addition to the ordinary measures, plugging the uterus or vagina, others tying the uterine arteries.

In choosing to do Cæsarean section the cervix is the determining factor, whatever the age or parity of the patient. The results of Cæsarean section, preferably by the low method of De Lee, are infinitely better than the older ways and means, and it is certain that this operation will become the accepted measure in all cases where the foetus is viable and efficient surgical care is available, for it has reduced the foetal and maternal mortality by one-third.

B. coli infections after obstetric and gynecological operations are so common a feature of the tropics that it may serve a purpose to quote the statistics which the writer has published in previous articles, with a view to helping the patient as well as the surgeon for nothing is more disconcerting than for a patient, shortly after an abdominal operation or confinement, to develop rigors or high fever for which no adequate explanation can be attributed.

In the tropics it is an error of human nature to explain all such adventitious fevers to the ubiquitous *Anopheles* mosquito, and from the point of view of the patient nothing is more disastrous, for she may be dosed or injected with quinine for several days with no effect, and matters made worse because the acid solution tends to increase rather than diminish the severity of the infection.

The writer has proved bacteriologically that 30.2 per cent. of the fevers subsequent to confinement in the tropics are due to *B. coli* infections, and that 10 per cent. of the fevers before delivery are due to the same organism. After plastic vaginal operation, 32.6 per cent. of cases have been shown to possess *B. coli* in the urine: 14 per cent. of all abdominal operation cases also have developed fever due to *coli* bacilluria.

The greatest pains have been taken to investigate the ætiology of these infections: the catheter, though possibly an occasional factor, could only be blamed in less than 5 per cent. of cases, for the greater percentage of the patients had no catheter passed. The infections are just as frequent in Indians as in Europeans; consequently diet can be no causal factor. It occurs in private patients with their own nurses as frequently as in ward cases. The most predisposing cause would seem to be retention of the urine for more than eight hours.

The writer has demonstrated that *B. coli* far outnumber all other organisms in nulliparous and parous vaginae in the tropics, and is frequently

the cause of those most distressing cases of vulvo-vaginitis in children of all classes in India. It is presumed, therefore, that under certain conditions of reduced resistance, these organisms are able to travel via the urethra to the bladder and pelvis of the kidney. Fortunately *coli* bacillæmia is very rare; in only one case, that of double salpingo-oophorectomy plus hysterectomy for endometriomata, out of 600 consecutive abdominal operations did this occur with a fatal result on the twelfth day.

Every gynæcologist should be on the *qui vive* for this infection in the tropics, and when any untoward fever develops a catheter specimen of the urine should be taken with every precaution. In the absence of an immediate bacteriological report, presumption of this infection may be made if the urine is acid and there is albumin present with pus cells in the deposit. The specific gravity is usually low, and the colour of the urine straw-like with a curious shot-silk like opalescence. Confirmation may be obtained by a blood count, for all *B. coli* patients show a marked leucocytosis. Moreover, despite the high fever, as a rule they do not complain of it or appear to be very ill. Oftentimes the tongue is clean.

Pending a cultural report, the patient should be put on drachm doses of potassium citrate in one pint of barley water five times a day, and a 2 per cent. aqueous solution of iodine (20 to 30 minims) injected intravenously daily. The vagina should be douched four hourly and the bladder washed out daily with a one in ten thousand solution of acriflavine. Urotropin should not be given while the temperature is up, but when it has subsided 15 grains three times a day for a week is useful in preventing a relapse, provided one drachm of acid sodium phosphate is given in water the first thing every morning.

Pregnancy Anæmia.

S. A. McSwiney (*Indian Medical Gazette*, September 1927) records a study of 43 cases of the anæmia of pregnancy, for which no obvious cause, such as malaria or hæmorrhage, could be found. The disease seemingly is much more common in India than in England, and Hindus provided most of the cases. The anæmia was much more frequent in early pregnancies, and there were five times as many patients under the age of 30 as over. As the incidence of twins was more than five times the usual, multiple pregnancy must be considered as a possible predisposing cause. The spleen was palpable in 7 patients, and the liver in 5. In extreme cases the anæmia was profound, and abnormal erythrocytes were seen in the graver cases, while the total leucocyte count showed no striking variations. Albumin was present in 21 cases, and markedly so in 5. Oedema of the feet and puffiness of the face were common, while a general puffiness of the whole body occurred in 14 cases. The patients were markedly prone to miscarriage and premature labour. The labours were noticeably bloodless, and postpartum hæmorrhage was observed in only one case. The author suggests

the following etiological theories: (1) The mother's restorative power to counterbalance the normal destruction of the red cells is inadequate. (2) The destructive action of the chorionic villi on the maternal erythrocytes is excessive, and comparable with the destructive action of the syncytium in chorion carcinoma. (3) Concealed syphilis must be considered, the Wassermann reaction being positive in 40 per cent. of the patients tested.

McSwiney advocates the use of iron and arsenic; plenty of liver, nourishing food, fresh air and sunshine, and whole blood injections. Whole blood transfusion is deprecated as being very dangerous, and weekly intramuscular injections of 15 to 20 c.c. instead are recommended. Specific treatment should be given when the Wassermann reaction is positive. As delivery favours recovery, pregnancy should be terminated, advisably by slow and gentle methods of induction. The patient should also be warned against another pregnancy.

With regard to the above views it should be added that Miss Balfour has proved that this anæmia of pregnancy is of the aplastic type. No absolute evidence has been furnished as to its causation. Miss Mehta has shown that 50 per cent. of cases had *Streptococcus hæmolyticus* in the urine, but the incidence of this organism in the urinary tract may be *post hoc* rather than *propter hoc*. The writer's opinion is that the work of Professor James Young most readily meets the problem, for he has proved that the end products of degenerated portions of placenta are the main cause; such products being of the tyramine and histamine group, are absorbed, and give rise to the pregnancy toxæmia. In one group of cases the brunt of the poisoning is on the liver and kidney, in another upon the cerebrum and peripheral nerves, in another upon the uterus and vascular system, giving rise to accidental hæmorrhage, and in another—the one we are considering—upon the hæmopoietic system, causing the classical idiopathic anæmia of pregnancy.

Taking into consideration the facts that this anæmia does not develop or show itself before the fourth month, that it is progressive, that the birth is premature in 90 per cent. of cases, that the foetus is a parasite draining the mother's vitality and very frequently killing her either before or shortly after its birth, despite all treatment including a liver diet and direct blood transfusion, there would seem no scientific justification for the continuance of pregnancy once a correct diagnosis has been made.

Therapeutic abortion having been decided upon, a decision as to the best method is of great moment, for although postpartum hæmorrhage is exceedingly rare in these cases, cardiac failure and shock with or without sepsis are extremely frequent. For years the writer has been advocating courageous realisation and action when dealing with these cases, and he firmly believes that

MARCH, 1928.]

in the tropics, when once this disease is established by a full blood report and picture, the best method of emptying the uterus is the application of X-rays to the uterus on three or more occasions. Thereby the foetus dies, and in the course of ten days or so is expelled as a foreign body, or can be facilitated to do so by the application of laminaria tents.

The X-rays should be applied by an expert and serve two purposes, (1) to empty the uterus, and (2) by their effect upon the ovaries, to inhibit the chances of another pregnancy.

The above views have been confirmed and put into practice by several American authorities during the last few years.

With regard to the matter of X-ray therapy to the ovaries by the inexpert, it is necessary to sound a word of warning, for considerable evidence has accumulated during recent years to show that should a patient conceive after X-ray application to the ovaries, there is an extreme likelihood of the foetus being born physically and mentally maldeveloped.

Epilogue.

The writer would like to stress the point how important it is for all teachers and professors in India to keep up to date in the practice of gynaecology and obstetrics, an art which is advancing by leaps and bounds hand in hand with pathology and biochemistry. In India, the morbidity and mortality from conditions which are preventable are enormous. Propaganda and the efficient teaching and training of students and post-graduates is therefore an absolute essential. The *laissez faire*, *kismet*, and "will of God" attitude as regards women's diseases, can no longer be excused by the plea of ignorance.

The great majority of medical students expect to practise medicine, but they are often unfitted for this end by their very training owing to the undue emphasis laid upon laboratory diagnosis and treatment, and the much reduced attention given to the training of their powers of observation. The raising of medical standards should result in attracting a higher grade of men to the profession than formerly, but in my judgment the student body of to-day in India is not of as high a grade as it was ten to fifteen years ago.

The cause of this may be that the fundamental knowledge of English in the modern student is not so great, but it would seem to me more probable that the present system of education is dwarfing instead of developing the average medical student.

There is too much spoon-feeding, with the result that although the student is taught more, he learns less. It has been said that "the medical student of to-day receives an intensive training in the fundamental sciences, a fairly comprehensive course in laboratory medicine, a very minor training of the study of the patient as an individual and not as a test tube, and practically no instruction in the relief of suffering, the ethics, and humanities of medicine." Such a

training is good enough may be to fit a man to do research or to work entirely within a hospital, but it is a very poor training for a man who wishes to enter practice.

This state of affairs can only be remedied by the proper selection of teachers of proved ability, wide interest, and clinical experience outside as well as inside a hospital. The mushroom growth of medical schools in India and the plethora of students in our universities make it all the more important that the teachers of individual subjects should be practical and not only theoretical specialists, for the great function of a medical school should be to train doctors to care for the sick and suffering in the community, on accepted principles of modern science. This cannot be done in India unless the teachers are men of outstanding merit and wide clinical experience, who are able to inspire students by their teaching, practice and example.

Current Topics.

The Indian Psychological Association.

We have been asked to bring to the notice of those of our readers interested in psychology and mental hygiene, the existence of this Society. It was inaugurated in January 1926, with the following objects:

1. The co-ordination in India of psychological research.
2. The publication of psychological works in English and in vernacular languages, and translations from existing foreign works.
3. The publication of a journal.
4. The organisation of lectures and scientific discussions.
5. The standardisation of the curricula in psychology at the different Indian universities.

In its first year the President of the Association was Dr. N. N. Sen Gupta, M.A., Ph.D., University College of Science, Calcutta, and there were 23 foundation members. Since then the Association has slowly made headway in spite of many difficulties and lack of interest. In 1927, the membership roll had increased to 64, the President being Lieut.-Col. O. A. R. Berkeley-Hill, I.M.S., and Secretary Mr. Gopeshwar Pal, Ballygunge, Calcutta. In January 1926, the Association commenced to publish a quarterly journal, the *Indian Journal of Psychology*. The numbers of this journal which we have seen are admirably edited and published, and contain papers of considerable merit, as well as abstracts and excerpts from European and American psychological literature. A presidential address by Professor Haridas Bhattacharyya, Dacca University, on "The Psychologist," for example, is an admirable essay on the present-day position in psychology. Other notable articles published are one by Lieut.-Col. Berkeley-Hill on the psychopathic child; one on sex in psycho-analysis by Dr. Girindrasekhar Bose, D.Sc., M.B., of the Calcutta University; and one on sterilization of the unfit by Dr. J. N. Pacheco of Ranchi.

It is stated that there are over three hundred institutions in this country which give lectures and courses of instruction in psychology, yet the position is very unsatisfactory, for the courses of instruction leave very much to be desired. In a few universities, such as those at Calcutta, Lahore and Dacca attempts are being made to put the teaching of psychology on a sound, practical basis, with the introduction of mental laboratory tests, and the like. Yet India surely is a country where the study of psychology should flourish

especially, since it includes so many ethnological races, so much ancient folklore, and so many psychological problems of interest. The Association was largely responsible for the formation of a Section of Psychology in the Indian Science Congress, and its activities are already wide; one of the most recent being a study of the mental status of children in institutions for mentally defective children in Calcutta by means of laboratory mental tests.

We would urge those who are interested in the subjects of psychology and mental hygiene in India to join the Association. The annual subscription is only Rs. 5, which includes the subscription to the quarterly journal. Communications with reference to membership, etc., should be addressed to the Secretary, Indian Psychological Association, Department of Experimental Psychology, 92, Upper Circular Road, Calcutta.

The Royal Institute of Public Health.

We have been asked to bring to the notice of our readers, and especially of those who intend to proceed to the United Kingdom for the purpose of taking a Degree or Diploma in Public Health, the advantages of joining the Royal Institute of Public Health, 37, Russell Square, London, W. C. 1. This institute was founded in 1886, and is under royal patronage. The objects of the institute are to promote the interests of those engaged in official public health work at Home and abroad, or in the public services, and also to aid the theoretical and practical investigation and study of all branches of state medicine (preventive medicine, toxicology, etc.). Its lecture and practical courses are recognised for the Diploma in Public Health examination by the different universities and medical corporations in England, Scotland, and Ireland.

Amongst other privileges of members are the following:—

1. Free delivery of the *Journal of State Medicine*, the official organ of the Institute, monthly. This is an ably run and well edited journal, containing papers of much interest in connection with public health, bacteriology, chemical analysis, etc.
2. Attendance at the Congresses of the Institute. These have hitherto been held annually; the one in 1927, having been held at Ghent, when Lord Burnham gave a very striking presidential address on the housing and slum problem in Great Britain.
3. Attendance at the special courses of lectures given at the Institute.
4. Specially reduced charges for the carrying-out of clinical and other scientific examinations in the bacteriological and chemical laboratories.
5. The use of a large reference library.
6. Facilities for meetings, conferences, etc.

The general course for the degrees and diplomas in public health comprises laboratory instruction; chemistry, with air, water, and food analysis, physics and sanitation; public health administration; fevers, climatology; bacteriology and parasitology; hygiene; hospital administration and clinical practice; and courses of lectures on special subjects.

Particulars with regard to the Institute and its courses of study may be obtained on application to the Secretary at the above address.

The New Year Honours, India, 1928.

THE following were the New Year Honours conferred on January 1st, 1928, on medical workers in India, whose recipients we beg to congratulate.

C.I.E.

Lieut.-Col. C. L. Dunn, I.M.S., Director of Public Health, United Provinces.

Knighthood.

Dr. W. J. Wanless, American Presbyterian Mission Hospital, Miraj, Bombay Presidency.

Kaisar-i-Hind Medal.

Miss E. Griffin, Superintendent, Lady Reading Health School, Delhi. Miss A. S. Graham, Superintendent, Lady Reading Health School, Delhi. Miss E. M. Farrer, Medical Missionary, Bhiwani, Hissar District, Punjab.

Kaisar-i-Hind Medal (Second Class).

Miss E. J. Holdforth, Matron, C. E. Z. M. Female Hospital, Larkana, Sind. Dr. C. D. Esch, Superintendent, Shantipur Leper Asylum, Raipur, C. P. Mother M. Antonietta, Nursing Sister, St. John's Leper Asylum, Mandalay.

Rai Bahadur.

Kishori Lal Chaudhuri, officiating Director of Public Health, U. P. Jai Gopal Mukherji, Reader in Rathology, King George's Medical College, Lucknow. Ram Sarup Srivastab, officiating Civil Surgeon, Bahraich, U. P. Lala Ram Chand, Civil Surgeon, Rohtak. Assistant Surgeon Mukand Lal, House Surgeon, Civil (Dufferin) Hospital, Delhi.

Rai Sahib.

Assistant Surgeon Madan Lal Raikhye, Punjab. Sub-assistant Surgeon Narendra Kumar Motilal, Bihar and Orissa. Sub-assistant Surgeon Amarendra Krishna Ghose, Bihar and Orissa.

Rai Sahib.

Trimbak Raghunath Gunes, Health Officer, Pandharpur, Sholapur. Sakbaram Ganesh Parajpe, Hon. Assistant Surgeon to H. E. the Viceroy. Sub-assistant Surgeon Vishwanath Narayan Shevade, Sutna, Central India. Bhashyam Mudaliar, Assistant Medical Officer, M. and S. M. Railway.

The Paradysentery Bacilli.

ONE of the most difficult problems in tropical medicine to-day is to determine the pathogenicity or otherwise of the numerous types of bacteria, which—though not belonging to the classical strains of the dysentery bacilli—are yet frequently isolated from the stools of patients suffering from dysentery, and which appear to be either truly causative of dysentery, or else associated with it. Some of these organisms, indeed, may either be lactose-fermenters, or late lactose-fermenters, giving red colonies on a plate of McConkey medium in 48 hours.

Sir Aldo Castellani—(as he now is, since his recent knighthood in the New Year Honours, 1928, in the United Kingdom)—has always been a pioneer worker in this difficult line of investigation, and a paper by him dealing with the whole subject in the *American Journal of Tropical Medicine*, Vol. VII, No. 4, July 1927, p. 199, is well worth the study of all laboratory workers in the tropics.

Sir Aldo Castellani proposes to divide the whole group of the dysentery bacilli and allied organisms into three primary groups, associated with three different clinical conditions, as follows:—

1. *Bacillary dysentery, sensu strictu*;—synonyms Shiga dysentery, Shiga-Kruse dysentery; due to dysentery bacilli which do not ferment lactose or mannite, and do not clot milk;—the Shiga-Kruse group.

2. *Paradysentery*, due to organisms which do not ferment lactose, cause acidity (only) in mannite, and do not clot milk;—the Flexner-Hiss-Russell group.

3. *Metadysentery*, due to organisms which do not produce gas in any sugar, but may cause acidity in lactose and clot milk, or ferment lactose with the production of acidity only without clotting milk, or clot milk without fermenting lactose. These organisms he proposes to relegate to the genera *Dysenteroides* and *Lankoides*.

In general litmus milk, lactose, and glucose are regarded as the three essential media by which differentiation of species and genera can be established, and no less than eleven different genera are established by the use of these media. A very important point which

Sir Aldo Castellani's researches have brought to light is that, whereas a single species of organism may produce no gas in any sugar medium, when two such non-gas producing organisms are grown in culture symbiotically in the sugar medium, gas may be produced. This phenomenon he proposes to call the symbiotic phenomenon, and he gives the following general account of it:

The symbiotic fermentation phenomenon has been described by me in previous publications. It may be defined as follows:—

"Two organisms, neither of which alone produces gas in certain carbohydrates, may do so when living in symbiosis or artificially mixed." For instance *B. typhosus* alone does not produce gas in maltose (acid only), *B. morgani* does not produce gas in that sugar (neither acid nor gas); the mixture *B. typhosus* + *B. morgani* produces gas. The phenomenon as I have shown in other publications may be of assistance in the classification of certain bacteria. The more important dysentery bacilli of the genus *Shigella*, may be differentiated as follows: The symbiosis *B. dysenteriae* Shiga-Kruse + *B. morgani* produces gas in maltose but not in mannitol; the symbiosis *B. paradysenteriae* var. *Flexneri* + *B. morgani* produces gas in maltose and mannitol; the symbiosis *B. paradysenteriae* var. *Hissi-Russelli* + *B. morgani* produces gas in mannitol but

TABLE.

Differentiation between *B. dysenteriae* Shiga-Kruse, *B. paradysenteriae* Collins var. *Flexneri*, *B. paradysenteriae* Collins var. *Hissi-Russelli*, by means of the symbiotic fermentation with *B. morgani*.

	Mannitol.	Maltose.
Symbiosis Shiga-Kruse + Morgani	0	G
Symbiosis Flexner + Morgani ..	G	G
Symbiosis Hiss-Russell + Morgani ..	G	0

0 = absence of gas; G = gas present.

not in maltose. The results of the symbiotic fermentation correspond to the results of the simple fermentation induced by the organisms themselves, viz., by symbiotic fermentation, gas is found in those carbohydrates in which the dysentery organisms alone produce simple acidity. The presence of gas, however, is a much more striking phenomenon and moreover, in certain cases, for instance, in the case of Shiga-Kruse with regard to maltose, gas becomes evident much more rapidly than acidity to litmus. With regard to the symbiotic fermentation phenomenon the reader may find all the details in previous publications, among which the papers in the *Journal of the American Medical Association* (February 20, 1926, vol. 86, pp. 523—527) and in the *Proceedings of the Society of Experimental Biology and Medicine* (1926, XXIII, pp. 481—488 and 1927, March, XXIV, p. 511).

In his final summary, the author writes as follows:—

Conclusions.

1. The dysentery bacilli may be conveniently grouped as follows:

- (a) *Dysentery bacilli, sensu stricto.*
- (b) *Paradysentery bacilli.*
- (c) *Metadysentery bacilli.*

The three groups have a very important characteristic in common: they produce no gas in any sugar. The first two groups are biochemically much more closely allied among each other than with the third group. The organisms of the first two groups never produce acidity in lactose and never clot milk; they differ, as well known, among themselves with regard

to mannitol: those of the first group (Shiga-Kruse) do not produce acidity in mannitol, those of the second (Flexner-Hiss-Russell) do. The organisms of the third group on the other hand either produce acidity in lactose and clot milk, or produce acidity in lactose without clotting milk, or clot milk without producing distinct acidity in lactose. The first two groups form the genus *Shigella*; the organisms of the third group form the genus *Lankoides* (milk clotted, lactose acid or no change), and the genus *Dysenteroides* (milk not clotted, lactose acid). The two genera *Lankoides* and *Dysenteroides* are very closely allied, and often organisms which at first are placed in the genus *Dysenteroides* have later to be placed in the genus *Lankoides*, as after a prolonged incubation they produce clotting of milk; it might therefore be advisable to combine these two genera into one genus, *Dysenteroides sensu lato*. The principal pathogenic species of the third group seem to be *B. ceylonensis* B, *B. ceylonensis* A and *B. metadysentericus*.

2. A somewhat similar nomenclature may be used to indicate the various types of bacterial dysentery.

- (a) *Bacterial dysentery sensu stricto*, due to *B. dysenteriae* Shiga-Kruse.
- (b) *Paradysentery*, due to the different varieties of *B. paradysenteriae*, due to the different varieties of *B. paradysenteriae* Collins (var. *Flexneri*, var. *Hissi-Russelli*, etc.).
- (c) *Metadysentery*, due to the metadysentery bacilli (Bacilli of genus *Lankoides* and *Dysenteroides*).

3. Certain authorities believe that the metadysentery bacilli, viz., bacilli of the *Lankoides-dysenteroides* group, may be identified with *B. coli anærogenes*, a bacillus which Lembke isolated from the stool of a dog in 1896; and Nabarro, who has carried out a very important investigation on the subject, is inclined to favour the opinion that the organisms isolated by me and later on by himself, Sonne and others are in fact identical with that bacillus.

I am inclined not to agree with this opinion, as since 1905 I have found constant differences between the principal species of the group, especially with regard to indol production and serological reactions. Some species of the metadysentery bacilli are pathogenic, others are not. Among the pathogenic ones are *B. ceylonensis* A, *B. ceylonensis* B, *B. metadysentericus*. These bacilli in addition to having been found in cases of typical dysentery have been found also in certain obscure types of colitis with or without fever in which dysenteric symptoms were absent.

India and the League of Nations.

(A lecture given by Colonel J. D. Graham, C.I.E., I.M.S., Public Health Commissioner with the Government of India, to the Rotary Club, Calcutta, on the 6th December, 1927.)

From the *Statesman*, 7th December, 1927.

Col. Graham, after remarking that India's birth rate for 1925 was nearly twice that of England and Wales, her death rate was twice that of England and Wales and nearly three times that of New Zealand, her infantile mortality rate was nearly 2-1/3 times that of England and Wales and nearly 4½ times that of New Zealand, said that the information furnished for the great group of infectious diseases of world import, namely, plague, cholera, smallpox, yellow fever, typhus, malaria and dysentery showed that if they excepted typhus and yellow fever, India was one of the world reservoirs of infection and the main reservoir of infection for plague and cholera.

The significance of these facts must be obvious to all. Briefly their implication was that India's house from the public health point of view was sadly out of order, and that this disorder required to be attended to. Till recently this seemed a matter which concerned India alone and it was largely in this spirit that this question was regarded in India. With the re-awakening

of interest in all social problems and the increased international activity regarding public health, and the prevention of disease which occurred after the Great War, it was evident that much in the realm of national disease which formerly passed unnoticed must now come into the limelight and be subjected to international scrutiny.

It was not enough for India to say that she was concerned with 300 millions of her own subjects and had no time to worry over the activities of other nations. She must be prepared to recognize that, in virtue of her important commercial position, she was an international offender—and a dangerous one as well—and in this spirit to set about tackling the problem which confronted her by employing an organisation capable of utilising for such purposes the most recent discoveries of research in regard to these diseases and disease problems which were peculiarly her own.

After dealing with early developments in the realm of protection from diseases, Col. Graham referred to the organisation of the League of Nations and more especially to that section of it dealing with health, and said that of special interest to India was the fact that their Public Health Commissioner was not only a member of the Permanent Committee of the Paris Bureau, but, since December 1926, had also been one of the 20 members of the Health Committee of the League, the President of which they had here in the person of Dr. Madsen of Copenhagen. Great Britain, the Dominions, the Colonies and the Indian Empire were represented by two members, of whom Sir George Buchanan of the Ministry of Health was the other.

What would perhaps appeal more directly to this meeting, however, were the activities surrounding the creation of the Epidemiological Bureau in Singapore. The present position was that 137 ports of Asia, Australia and the East Coast of Africa were now sending weekly information to the Bureau, all of which was incorporated in the broadcast coded message sent out from Singapore. In addition the powerful German apparatus at Mauern which picked up the Saigon message and rebroadcasted it for the benefit of Europe, so that by Saturday of each week the infectious disease condition of 137 ports of the East up to the previous Saturday midnight was known everywhere in Europe, Asia and Africa.

It was, added Col. Graham, almost a platitude to state that much of the economic loss and human suffering going on in India to-day was avoidable. Experience, not only throughout the British Empire but also in other countries had demonstrated this. With such an array of examples it was not for India to say that so far as she was concerned prevention was impossible. It was becoming increasingly evident that a section of the Indian community was thinking seriously on these public health problems. Amidst much futile and destructive criticism of State and municipal effort here and there valuable and suggestive constructive criticisms could be met with, which went to prove his contention.

A well-informed Press, both European and vernacular, but especially the latter, would be one of their most powerful allies in this great fight; for fight it must be, even to waging war and carrying it right into the enemy's camp. This was a work which had to be done for the benefit of Indians. To be effective it must carry conviction and establish its position against immemorial conservatism and tradition; it must therefore be done by Indians. It presented a grand and unlimited field for Indian public health workers, be they male or female; but it was well to recognize that the improvements could not be achieved when the expert labourers were few in number, that these could not be increased to the requisite number without a careful system of specialized training institutes or schools devoted to public health teaching and research, and that this could not be done without adequate financial support.

Col. Graham looked at the entry of the League into public health matters as an innovation which must bear fruit and do good. It would help to break down

more rapidly many barriers which had little to recommend them, and, whilst bringing home to India what other countries were doing and had done, it would incidentally enable Indians to realize the leeway which had to be made up. They would realize how European death rates had come tumbling down, and how general mortality rates had fallen; they would ponder over the fact that, in 1885, the expectancy of life, in the United States of America was 40 years whilst now it was 58; they may be tempted to probe further into the reasons for this and into the story of the work of voluntary organisations. In this way it was hoped that many Indians might rise who would help to form and lead public opinion in these matters.

In conclusion Col. Graham said that a few years ago India might have been excused for delinquency in international matters, but a time had arrived when India, through her obligations to the League of Nations Assembly and through her commerce, was now called upon to take her position as one amongst the comity of nations. If she would do so creditably in so far as public health was concerned, she must be prepared not only to receive information but to give it, not only to demonstrate her institutions and her organisation to inquirers from outside but to make a serious attempt to establish a public health conscience and to act on it. It was only thus that she would gain that confidence of others which was so necessary for her both commercially and hygienically.

A short discussion followed, in which several of the delegates attending the Eastern Tropical Conference took part.

The Tobacco Habit.

By W. E. DIXON, M.D., F.R.S.

(*British Med. Jour.*, October 22, 1927, p. 719.)

Europe learned the use of tobacco from the American Indians. Tobacco is an Indian word, but nicotine is named after the French Ambassador in Lisbon, Jean Nicot: he grew tobacco seed in his garden, and vaunted the leaves as a cure for all external diseases.

Tobacco was brought into England by Ralph Lane in 1586.

A reaction against its use arose in the fifteenth and sixteenth centuries. James I published in 1603 a pamphlet entitled "*Misocapnus seu de abusu Tabaci Lusit reginus.*"

The Tsar Michael punished his soldiers with the rack and knout for smoking.

The use of tobacco has become universal throughout the world.

The smoke emitted from any smouldering vegetable matter, including tobacco, contains ammonia gas and pyridine or pyridine derivatives. These are responsible for the morning cough, the irritation of the throat and tongue, and the conjunctivitis of the cigarette smoker.

In tobacco smoking the only serious effect of these bodies is the local irritation, since their specific effects are insignificant in comparison with those of other substances which are present in this smoke.

The United States Bureau of Mines found that the CO concentration of the air of a room did not rise to more than 0.01 per cent., and the maximum blood saturation of the subjects exposed to this atmosphere was only 5 per cent. Nevertheless this is more than enough seriously to affect sensitive people. Cigarette smoke yields from 0.5 to 1 per cent.; the pipe 1 per cent. or more, and the cigar 6 to 8 per cent.

Tobacco smoke reaches the mouth freely diluted with air, and the amount of CO absorbed from the buccal cavity is negligible, so that pipe and cigar smokers who do not inhale have little to fear from this poison. Cigarette smokers who inhale would absorb a large proportion of the CO which reaches the lungs, since the affinity of CO for blood is more than two hundred times that of oxygen. Hartridge

found 6 per cent. CO in the blood in one cigarette smoker who was by no means excessive in his habits. By far the most important constituent of tobacco is the volatile alkaloid nicotine.

During the slow combustion of a cigar as in ordinary smoking there is an area immediately behind the point of combustion in which the water and other volatile substances condense. During aspiration the hot gases are drawn through this hot moist area and carry with them the volatile principles, of which nicotine is the most important. Hence the smaller this moist area behind the point of combustion—which means, the cooler the smoke or the more complete the combustion—the less likely is the smoke to contain volatile toxic bodies. It follows that a cigarette or slender cigar which is well cooled will yield fewer of these products than a thick cigar, and many smokers can testify that a fat cigar has a much greater effect than a long slender cigar of similar tobacco. This also explains the unpleasant effects of relighting a half-finished cigar or pipe.

Tobacco may contain anything from 1 to 8 per cent. of nicotine; Havana tobacco has about 1.5 per cent.; Maryland 2 per cent.; Virginia 6 per cent.; Kentucky 8 per cent.

The amount of nicotine in tobacco is no criterion of the amount in its smoke. For example, mild honeydew contains only 1.6 per cent.; whilst Cavendish may contain as much as 3.8 per cent.; if these two are smoked under identical conditions the Cavendish naturally yields the larger amount of nicotine in the smoke. But Cavendish smoked in a cool pipe or one provided with a filter will affect the smoker less than the honeydew smoked in a hot pipe. In the churchwarden pipe the opportunity for the nicotine to condense is such that the smoke is almost freed from the alkaloid; and in cigar and cigarette smoking the degree of moisture, the tightness of packing, and the thickness of the cigar or cigarette are the most important factors in determining the amount of nicotine which will be present in the smoke. Habermann and Ehrenfeld state that two-thirds of the nicotine of some kinds of cigars passes over in the smoke; if a cigarette smoker were to puff ten cigarettes on end he would certainly absorb 20 to 30 mg. of nicotine—enough to produce a profound physiological effect, though, administered in this way, perhaps ten to fifteen times under the lethal dose. The amount of nicotine in pipe and cigar smoking is much higher. In our experiments cigar smoke contains about twice as much nicotine as cigarette smoke.

Nicotine is one of the most fatal and rapid poisons known; it acts as quickly as prussic acid, and two drops placed on the tongue of a dog will kill it almost immediately. The lethal dose for a man is 60 to 120 mg. The nicotine present in one cigar if injected intravenously would represent two fatal doses to man. It is therefore somewhat remarkable that fatal nicotine poisoning is not more common. Nevertheless the careless use of tobacco infusions in enemas, the occasional swallowing of tobacco leaves, or even carrying tobacco leaves next to the skin for smuggling purposes, have all led to fatal results.

Various methods have been adopted to eliminate the nicotine from the smoke and the juice which is apt to form in pipes. A porous substance may be put into the stem of the pipe; the space for cooling and condensation may be increased, or some substance which facilitates oxidation may be placed in the bowl of the pipe. These last pipes are called catalytic, and the bowls are lined with some metallic oxide, like that of platinum, in a fine state of division. By passing tobacco smoke over the catalyser formol is formed and the nicotine and pyridine derivatives are decomposed. These pipes have not, however, found favour.

Improved methods of removing nicotine are now being experimented with abroad. Boxes of cigarettes and tobaccos in various forms are treated with superheated steam; by this means practically the whole of the nicotine is said to be removed and the tobacco is

left nicotine-free; the nicotine has a ready sale for agricultural purposes. I have had no opportunity, however, of experimenting with these products.

Continuous smoking for several years not infrequently produces signs of chronic irritation in the mouth, throat, and larynx—sore tongue, morning cough, hoarseness, tonsillitis, or chronic bronchitis, these effects are most marked in the cigarette inhaler. When the smoke is concentrated on one portion of the tongue for many years, which may occur especially in pipe smoking, this constant irritation is said to favour the formation of epithelioma of the lip and tongue if the quantity consumed is large or the smoker predisposed.

Smoking is reputed amongst the public to have an antiseptic action, and is sometimes indulged in nominally for this purpose. Puntoni and others have shown that tobacco smoke has a strong disinfectant action *in vitro*. When the smoke is drawn into the mouth, however, the action is attenuated by the saliva and mucosa, and its antiseptic effect is negligible.

Smoking is indulged in by man because of its sedative action, and this is due solely to nicotine absorption. Nicotine stimulates all nerve cells throughout the body without exerting any kind of selective action.

The commonest symptoms of smoking are loss of appetite and chronic intestinal catarrh. The smoker's lack of appetite, Sir Humphry Rolleston thinks, is not altogether an evil, since it limits the consumption of unnecessary food. Nicotine, and tobacco smoking, by stimulating the autonomic ganglia, increase the secretion of the alimentary glands, and later, after the smoking has ceased, depress them; hence the salivation during smoking and the dry mouth the following day. It is well recognized that in certain persons excessive smoking leads to gastric hypersecretion; hyperacidity is the most common disturbance, and gastritis acida is one of the most frequent results. Hurst believes that tobacco smoking is one of the most frequent causes of hyperchlorhydria.

On the musculature of the alimentary canal the action of tobacco is equally well marked, the automatic movements are first inhibited and later augmented, as a result of stimulation and later depression of the autonomic nervous system.

The mild laxative action of tobacco smoke may be explained by the ultimate depression of the inhibitory cells whereby the motor nerves assume an undue influence on the automatic movements.

Hunger is due to certain well recognized automatic contractions of the stomach; smoking definitely inhibits these. All observers are agreed that the use of tobacco increases the pulse rate from five to ten beats a minute, and in the case of the man who is continually smoking the increase of rate becomes permanent, but this condition produces no apparent disadvantage.

This increase in the pulse rate is associated with a small rise in blood pressure; for the moderate smoker the rise does not usually exceed 20 mm. of Hg. systolic, and 8 mm. of Hg. diastolic, and is usually even less. The rise begins a few minutes after the smoking has commenced and is maintained throughout the smoking period.

These changes from the normal are, after all, usually small and give rise to no symptoms, but the evidence available suggests that they cannot be regarded with indifference. It is a maxim with those who are in training for athletic events that smoking must be entirely eschewed. This prohibition, no doubt adopted in the first place as the result of experience, has become a tradition.

Of the more definite effects which cause patients to seek advice some are palpitation and arrhythmia, which are relatively common in the young; they disappear if the smoking is stopped, though in pronounced cases, only after the abstinence has been continued for many months. The arrhythmia is functional and is usually due to extra-auricular systoles.

Arrhythmia may occur at any age but is more noticeable after 50; this may be due to a loss of tolerance which is known to occur in later life.

Another symptom which may arise from excessive smoking in later life is anginoid pain, which, according to Osler, rarely approximates to true angina. Turney says that it is associated with vasomotor disturbances and tends to occur after meals or in the night rather than after exertion.

Arterio-sclerosis is easily produced in animals, especially rabbits, by the injection of nicotine.

There is a consensus of clinical opinion that immoderate smoking favours arterio-sclerosis. Pawinski states that 42 per cent. of 1,000 cases of coronary sclerosis had histories of immoderate smoking.

Nicotine affects the brain and cord, it increases spinal reflexes and removes certain inhibitions.

A large experience of examination papers of medical students has enabled Dr. Dixon to pick out with certainty the heavy cigarette smokers, from the irregular character of their writing. If the habit is broken the writing at once improves and the vertigo disappears. These effects are exactly those of CO poisoning, and can be explained on this basis.

Habitual smokers are agreed that the weed acts as a mild sedative to the central nervous system; the type of action is of a somewhat remarkable character and may offer an explanation of the widespread use of tobacco.

Mental efficiency tests have not been very convincing. In Berry's experiments smoking enabled his subjects to do more rapid and correct arithmetical addition; but the nicotine here was not the determining factor, the aroma, and holding an unlighted cigar, or chewing substances like gum all had some effect.

The habitual smoker, when deprived of his smoke for some hours, showed diminished accuracy.

Many observations have been made by merely comparing the efficiency, mental or physical, of smokers and non-smokers. All these experiments are so difficult to interpret that their value is negligible. Generally they show some inferiority of the smokers. This is true of observations of scholarship, endurance of telegraph workers, scholarship and physical efficiency, and resistance to tuberculosis. The apparent inferiority may be the cause or the effect of the tobacco habit. Those who are handicapped by neurosis or other form of inferiority would succumb most easily to the euphoria of smoking.

It must be conceded that ordinary smoking in normal people does not lead to nervous disturbances. Excessive smoking is another matter, and may produce anxiousness and insomnia. Every smoker knows that a stronger cigar than usual may keep him awake, though usually the effects of smoking are soothing and favour sleep.

Tobacco amblyopia stands alone in mischiefs so grave. It was noticed by Mackenzie in 1835 and observed accurately by Hutchinson in 1864. The sight gradually becomes dim with central scotoma, some derangement of accommodation, and often dilatation of the pupil. This condition is associated with retrobulbar optic neuritis, and recovers if smoking is stopped; when degeneration has set in, however, abstaining from nicotine will only arrest further progress.

Androgé in a critical analysis of 48 cases of amblyopia from axial neuritis due to nicotine, says the quality of the tobacco is at fault; it was imperfectly dried, which means that the percentage of nicotine in the smoke is much greater than usual.

The rapidity with which people become accustomed to nicotine is remarkable. The degree of tolerance varies in different people, but it is never absolute. Wahl in 1920 found that non-smokers suffered from nausea and vomiting after taking by the mouth 1 to 2 mg. of nicotine. On the other hand, smokers required more than 8 mg. to produce the same effect.

Experiments of Dixon and Lee made on rabbits showed that repeated injections of nicotine into an

animal give to the tissues, and especially the liver, an increased power of destroying the toxicity of the nicotine. It is easy to conceive of several ways in which this might be brought about, but some of these possibilities may be eliminated by experiment.

Several clinicians have recorded cases showing a gradual drop in tolerance with advancing years. Finkelnburg says that patients, when once they have experienced symptoms of poisoning by nicotine, the particular form of which is immaterial, become more susceptible to the action, so that a smaller quantity of tobacco will reproduce the toxic symptoms.

The habit of smoking is sometimes referred to as an addiction. Rolleston discusses this question, and all it is necessary to say here is that addiction is a relative term; the most powerful drug of addiction is probably heroin, and then follow cocaine, morphine, Indian hemp, opium, alcohol, and last tobacco.

Reviews.

AN INTRODUCTION TO MEDICAL PROTOZOOLOGY.—By Lieut.-Col. R. Knowles, I.M.S., Professor of Protozoology, Calcutta School of Tropical Medicine. 1928. Pp. 887, with 15 coloured plates and 174 text illustrations. Calcutta: Thacker, Spink and Co. Price, Rs. 25. London: W. Thacker and Co., 2, Creed Lane, London, E. C. 4. Price, £2-2-0.*

THIS manual is an ambitious extension of the small book *Lecture Notes on Medical Protozoology* published by the same author in 1923, which has now assumed the proportions of a textbook.

At first sight one was inclined to think that Col. Knowles' praiseworthy effort would be eclipsed by the splendid two-volume treatise recently published by Professor Wenyon, but on going through this book in detail one feels sure that it will serve a purpose which the more pretentious volume will not meet.

As befits a book written primarily for students and for a more limited audience, Col. Knowles' book is written in his well known facile (almost chatty) style which makes the book more readable than is the case with most books on protozoology.

He has freely acknowledged the abundant help he has received from such authors as Wenyon, Dobell, and Patton and Cragg, and such assistance (which the author calls "looting") is evident on almost every page. The reviewer has no hesitation in declaring on behalf of the Indian and tropical workers in general who will use this book, his admiration for the generous way in which these distinguished authorities have given their whole-hearted assistance to Col. Knowles in the compilation of this book and this is further evidence of the kindness which many workers in distant countries constantly receive from their more fortunately placed colleagues at home.

On proceeding to examine the book one finds a number of coloured plates, many full paged reproductions in monochrome, and a still larger number of illustrations in the text but there is no list of these given at the beginning of the book as is customary. We think that in future editions this should be rectified for the first two classes of illustrations at any rate. The coloured plates are for the most part good and bring out the finer points even if the colours are in some cases not quite true to life. The full page reproductions in monochrome (generally borrowed from other authors) are of very varying merit, many of them being weakly produced giving faint and indefinite outlines and a lack of contrast as if from over exposure of the negatives. This is distinctly a weak point in the

* It is perhaps unusual to publish two reviews of the same book; but, as we have received one from Lieut.-Col. F. P. Mackie, I.M.S., who is an experienced protozoologist, and one from Mr. R. Senior-White, F.E.S., who deals chiefly with the entomological aspect of the book, we publish both.—Editor, I. M. G.

production of the book and should be improved in subsequent editions.

The subject matter is arranged in the usual way and the *Rhizopoda*, *Mastigophora*, *Sporozoa*, and *Ciliata* successively dealt with. The intestinal amœbæ are clearly described and the author has wisely followed Dobell and his school closely, whilst not failing to castigate others (including himself) for the complexity which has shrouded this subject in the past. Even now despite the clearness of the text and of the illustration it is only the expert who will be able to differentiate the various intestinal amœbæ from one another. For the average worker all that is essential is that he be able to say with confidence "this is an *Entamoeba histolytica* or its cyst," the rest are of small importance and the writer has wisely stressed this point and following Wenyon, Dobell and others has laid down criteria which enable the distinction to be made with reasonable certainty. The reviewer agrees that amœbæ are too often diagnosed as pathogenic and that emetine is given far too frequently, and in his opinion (speaking for Bombay at any rate) amœbic dysentery is an uncommon disease.

The cytology of dysentery stools is clearly explained and it is shown that in most cases a confident diagnosis of acute bacillary dysentery can be given by the simple examination of a wet specimen so that serum treatment may be begun at once. This procedure has been followed in many laboratories for some years past. The appendix on the "Laboratory Examination of Dysentery stools" pages 101-111 is the most valuable part of this section.

To turn to the *Mastigophora* this section is of somewhat unequal merit. Looking to the complexity of the intestinal flagellates and their ill-defined position and relationship there has been an unnecessary amount of space devoted to them, with the result that the student will be confused with so much detail. Col. Knowles admits (and the reviewer agrees) that the pathogenicity of none of them has been proved and in a book which is of the nature of a practical guide, it would have sufficed to have given a much less exhaustive discussion of this class of commensals.

The chapters on human trypanosomiasis must be in the nature of things a frank compilation, but nevertheless a reasonably clear and accurate summary of the enormous volume of recent literature has been given.

We should expect on the contrary that the chapters on leishmaniasis would be in a different category and we are not disappointed. The fascinating history of this disease has been set out at great length and a fair picture has been presented of the labours of a succession of workers in this field.

Col. Knowles is rather hard on those who worked for years on the bed bug theory of transmission of kala-azar, forgetting that many of those who did so (including himself) approached the subject not as believers or disbelievers but as those attacking the prevailing hypothesis which had to be proved or disproved. More than a half of the scientific workers of to-day are engaged in proving or disproving the theories of others and it is one of the "last infirmities of noble minds" that induces distinguished people sitting in armchairs to let off a series of suggestions which it takes an army of workers to prove or more commonly to disprove. There should be a censorship of scientific theories before they are cast on to the world. The bed bug theory of kala-azar is a case in point.

Knowles prefers to retain the genus *Leishmania* in place of that of *Herpetomonas*, though the reasons for doing so are not entirely satisfactory, and certainly not the naive one that Leishman's name will otherwise cease to be associated with the parasite he discovered.

The reviewer is glad to see that the author adversely criticises the extraordinary findings of Laveran and Franchini and of Pantham and Porter on the relationship between the herpetomonads of insects and their transmissibility to vertebrate hosts. Such observations

should have provided work for our censor before being divulged to the scientific world.

The *Sporozoa* are fully dealt with, but the coccidia, especially the rare migrants of the human intestinal canal, receive an undue amount of attention.

The well worn subject of the plasmodia is well and clearly dealt with and in this section the coloured plates are good and the coloured scheme of transmission is excellent.

The chapter on the *Ciliata* is also good, but again unnecessarily prolix considering the unimportance of the subject to human protozoology.

The next lecture is devoted to the Spirochaetes and the author begins by stating his belief that these are not protozoa but probably bacteria and then, as it might appear illogically, proceeds to devote some sixty pages to their consideration in a book on protozoology. It is true that on the whole the evidence is more in favour of excluding the spirochaetes from the protozoa, but if they are to be described in a book like this it would have been better to have used the word (coined by Hæckel) Protistology, which includes the most primitive forms of both animal and vegetable life, that is to say both the Protozoa and the Protophyta. However, as Wenyon and most other protozoologists have adopted the same somewhat illogical course, criticism of this book is disarmed. The name *S. carteri* for the Indian spirochaete is attributed here and generally elsewhere to Manson, whereas it was first given by the reviewer early in 1907 before the appearance of Manson's edition wherein it also appeared. The granule phase of spirochaetes is referred to as doubtful and this represents the opinion of many experienced workers on the subject. There is a good description of the spirochaete of syphilis and some good practical hints as how best to reveal it.

There is a good summary on our knowledge of the *Chlamydozoa*, or rather of our lack of it and special reference is made to rabies under this head. Good as the appendix on antirabic treatment may be, it seems out of place in a book on protozoology and no one would look for it or expect to find it here.

The last 140 pages of the book are devoted to laboratory methods and we have no hesitation in saying that this is the best part of the book. The chapter dealing with sources of material is especially useful to those who have to provide students with preparations. Space does not permit the reviewer to refer in more detail to the excellent chapters on insect dissection, cultural methods, and all the practical technique of everyday laboratory work. Experience and practice is evident on every page and this information will be of much use to all laboratory workers whether protozoologists or otherwise.

The book ends with a copious bibliography which does ample justice to workers in India, some of whose writings have often escaped the notice of European and American writers, and the index is full and well arranged, whilst important subjects are indicated in heavy type.

On the whole we may congratulate Colonel Knowles on having produced a book adequately reviewing existing knowledge, whilst adding not a little from his large personal experience. It is written in a pleasant and easy style and the book is one which should take a high place in the routine work of the practical protistologist.

We take it that the book is designed not so much for the bookshelf as for the laboratory bench of the microscopist in the tropics and for this reason it is questionable whether in future editions the book should not be issued in two smaller and more handy volumes. One of these would contain the text in the form of a handbook and the second volume the valuable information on laboratory methods. In any case the text might profitably be cut down to eliminate much of a controversial and historical nature, leaving the discussion of such aspects of the question to the more formal and more critical textbooks.

Col. Knowles has produced an eminently useful and readable book and one which will find favour not

only with the students of the Calcutta Tropical School but also with the wider circle of laboratory workers in the tropics.

F. P. MACKIE.

The first impression left on one's mind by a study of this work is the amazing erudition of its author,—the second that were one a student, it would be impossible to assimilate sufficient of its contents to pass the final examination. Almost one sighs for a re-issue of the book's predecessor, *Lecture Notes on Medical Protozoology* as being more suited to the needs of the student who has a dozen other subjects to study simultaneously.

Be this as it may, the book will be a precious possession to the worker who wishes to continue the study of the subject further than the extent necessary merely for examination purposes, and one cannot help thinking that it was the fostering of this class of worker, now all too rare in India, the general professional man who makes a life study of one special subject of his profession, that was the primary object in the author's mind. The few such who exist in India will be for ever grateful to him. The mere diploma-hunting student gets what he wants of laboratory technique spoon-fed to him, the professional laboratory worker has at his disposal the resources of his Institute's library, but the lone man in the jungle, who most of all has at his door the protozoological rarities, has hitherto lacked a concise set of laboratory "tips," such as part II of the book is replete with, as much as he almost invariably lacks the resources of an adequate library.

The writer cannot attempt to criticize the book as a protozoologist of equal standing with the author; he can only do so from the viewpoint of the past student now engaged in one small special domain of applied biology. From this standpoint he would venture to remark as follows:—

Out of the plates of the amœbæ and their cysts, he would have liked to have had a composite one of all stages of *E. histolytica* and *E. coli* apposed, as these two species alone affect the average clinician and general pathologist in a small station. The discussion on pp. 96–100 of the possibility of other entamœbæ is likely to confuse the student, and seems in any case more suited to a separate paper than for inclusion in a textbook of this nature. The appendix on page 101 on the examination of the dysenteric stool will be invaluable to just the types mentioned above. On page 150 a key on entomological lines to the various intestinal flagellates is a desideratum. It has always surprised the reviewer that medicine makes so little use of this universal zoological and botanical aid. By such means, for instance, "differential diagnosis" would be enormously simplified.

In figure 37 on page 160 *Leptomonas* has been used instead of *Herpetomonas*, whereas the fact that the two are treated as if synonymous is not stated until seven pages further on. In spite of the author's preference for accepted names, according with diagnostic terms, there can be no doubt on the evidence he himself quotes that *furunculosa* is the correct name for the parasite of oriental sore.

The true history, from one engaged in it, of the work on the transmission of kala-azar will make the book for ever of value as a historical document. To one who had the privilege of working in Patton's laboratory during the later years of his bed bug work, however, the effort wasted on the bed bug merits neither the epithets "amusing" or "sorry," but rather sympathy with one of the ablest and keenest of living protozoologists who followed a wrong side-path and thus left to others more fortunate than himself the results of eighteen years of the hardest labour.

A point not touched on is why kala-azar in Europe is purely an infantile disease.

On page 281 an extremely lucid summary of the pathogenic trypanosomes is given. Passing to the development in *Glossina*, the writer, as primarily an

entomologist, most strongly shares the author's doubts as to the existence of a slit in the hypopharyngeal wall through which trypanosomes passing forward from the gut enter via the labial cavity. As he remarks, one would not expect such an aperture in an ectodermic structure, which would have to be sphincter muscled unless salivary fluid were to be allowed to enter the labial cavity at this point, instead of near the tip of the proboscis, in which case the forward extension of the hypopharynx would be useless. The slit, moreover, would be valueless to the fly, and only play a part in the life-history of the trypanosome, which, presumably developed from a herpetomonad, must have originally found exit by the posterior route. The writer prefers the theory of Robertson that the salivary glands are invaded via the tip of the proboscis, improbable as this seems from the protozoological standpoint. As the author points out, Lloyd and Johnson had no opportunity of cutting sections to confirm their hypothesis. It might be added that figs. 59 and 60 are not from the 1925 paper of those authors, as quoted in the bibliography, but from their paper in *Proceedings of the Royal Society of Tropical Medicine and Hygiene*, xviii, 243, December 1924.

In connection with trypanosomes the final paragraph on page 310 should be pondered by all who doubt the advisability of including mention of the related parasites of animals in works dealing with human diseases.

On page 320 it is stated that fish trypanosomes are conveyed by leeches. Are there not also Copepods so engaged?

The reviewer is glad of the pronouncement on page 369 of the original Arthropod origin of the malaria parasites. This view, which is his own, is directly contrary to that of a well-known Indian malaria worker whose answer to this will be eagerly awaited.

The book is marred by few errors. Fig. 9 on plate 80 is not to be found. *Cardium edule* is hardly a snail in the ordinary sense. *Spirulina* is usually accepted, on account of its colour, as a Cyanophyceous alga. As seems inevitable in Indian publishing, however, the illustrations, magnificent in the original, have been but poorly reproduced, and whilst this can cause nothing but sympathy for the author, it casts a slur on the imprimatur of the well-known firm on the title page.

The book may be confidently recommended to all workers in the field of protozoology, medical and veterinary, and most especially, as stated before, to the lone worker everywhere.

R. S.-W.

PRACTICAL BACTERIOLOGY, BLOOD WORK AND ANIMAL PARASITOLOGY.—By E. R. Stitt, A.B., Ph.D., Sc.D., LL.D. Eighth Edition. London: Messrs. H. K. Lewis and Co., Ltd., 1927. Pp. xv. plus 837, with 1 plate and 211 other illustrations containing 683 figures. Price, 24s. net.

SURGEON-GENERAL STITT has a genius for writing students' textbooks; this one is now in its eighth edition and like its smaller predecessors it is crammed with well selected and clearly expressed information. The earlier editions achieved remarkable popularity all over the world, although they were far from being so complete or perfect as their latest successor. Stitt knows exactly what the student needs, a clear dogmatic account of the most important facts and methods: it is for this reason that the student and elementary worker finds his books so satisfying. Bacteriology, serology, blood examination, animal parasitology, protozoology, medical entomology, medical zoology, laboratory methods of examination are succinctly dealt with in a handy volume of 850 pages. An astonishing amount of useful instruction has been presented: those who know the book already will hasten to obtain this edition which has been greatly improved by the collaboration of many experts: those who do not know it will be well advised to buy a copy at the earliest possible moment. It is not an advanced worker's book but there are few who will not obtain many valuable hints from it; junior laboratory workers and medical

MARCH, 1928.]

men in general will find it a "ready help in time of trouble."

J. W. D. M.

THE AMERICAN ILLUSTRATED MEDICAL DICTIONARY.—By W. A. Newman Dorland, A.M., M.D., F.A.C.S. Fourteenth Edition. London and Philadelphia: W. B. Saunders Co., 1927. Pp. 1338. Price, 35s. net.

There is a remarkable thirst for medical dictionaries; Dorland's has gone through fourteen editions since 1900; although only two years have elapsed since the thirteenth edition was issued there are no fewer than two thousand new words in this new issue. The completeness and accuracy of Dorland's dictionary are universally admitted, its attractive get up and handiness have probably played important parts in ensuring its popularity. It is appalling to think that something like 70,000 technical words are employed in medicine and that new terms are being added with ever-increasing frequency. The proper place for most of these is in a dictionary which can contain them without damage to its structure, whereas the human brain which might attempt to encompass them would have room for nothing else. Presumably such words as "laparohysterosalpingo-oöphorectomy" have their uses, but they are certainly terrifying. About five hundred persons have their names associated with a special type of operation and it is likely that the list is far from complete. It is not to be expected that all the information contained in such a book is accurate, for example, kala-azar is said to be "transmitted by the bite of the sand-fly, *Phlebotomus argentipes*, perhaps by the Indian bed-bug and by a mosquito, *Anopheles punctipennis*." We are glad to notice that no countenance is given to the very prevalent error of pronouncing chenopodium, chinolol, plasmochin, etc., as if the ch were soft as in choice; the correct method is with a hard ch as in the word chemist. The book is well worth buying not merely as a book of reference but also as a source of useful and interesting information.

J. W. D. M.

PHYSICAL DIAGNOSIS.—By Richard C. Cabot, M.D. Ninth Edition. London: Baillière, Tindall and Cox, 1927. Pp. xxii plus 536, with 6 plates and 270 figures in text. Price, 25s. net.

This is the ninth edition of Cabot's well-known book on "physical diagnosis." It has been thoroughly modernized and includes reference numbers to a set of gramophone records which will soon be on the market and will illustrate the various abnormal sounds heard in the heart.

Only the methods with which Dr. Cabot is familiar have been dealt with, but the reader will agree that these include all that the general practitioner can be expected to know.

This is eminently a book for general use; it is not an encyclopædia of diagnosis, but its value to the student and practitioner is all the greater because it selects the procedures which are in general use. It is a book which can be heartily recommended.

Annual Reports.

ANNUAL REPORTS OF (1) THE NATIONAL ASSOCIATION FOR SUPPLYING MEDICAL AID BY WOMEN TO THE WOMEN OF INDIA. (2) THE VICTORIA MEMORIAL SCHOLARSHIPS FUND. (3) THE LADY CHELMSFORD ALL-INDIA LEAGUE FOR MATERNITY AND CHILD WELFARE. FOR 1926. CALCUTTA. GOVERNMENT OF INDIA CENTRAL PUBLICATION BRANCH. PRICE NOT STATED.

THE introduction of these three reports in one annual volume is welcome, for it enables the reader to obtain

a more or less bird's-eye view of the activities of medical women in India. The volume is admirably illustrated, a photogravure portrait of Lady Irwin forming the frontispiece, and illustrations of the Lady Reading Health School at Delhi and kindred institutions showing that Imperial Delhi maintains its style of beautiful buildings in medical matters as well as in others. A useful map of India at the beginning also shows how widespread are the activities of the organisations concerned, though Burma, we note, appears to be very blank.

The Countess of Dufferin's Fund was inaugurated in 1885 to attempt the colossal task of providing the women of India with medical attendance by women doctors. Since its inception, it is claimed that the Provincial administrations—though they have contributed to the Fund—have not done much to further this object. It may be claimed that such an object tends to keep alive the purdah system, but this is an obvious fallacy; the purdah system is there, and it will continue, despite the desire of all sanitarians to the contrary; hence, for perhaps the majority of the women of India, medical assistance must be provided by skilled women doctors and trained female assistants. There would be no Indian girls' schools in this country if there were no women teachers, and the analogy applies in medical matters.

The report shows that 256 lady students are studying in India for a medical degree, and that four teaching medical institutions are for women only; whilst there were 105 lady students out of this total of 256 in the Lady Hardinge Medical College, Delhi, during the year. This college is staffed by 8 officers of the Women's Medical Service, India, and these professors have 200 beds under their control in the attached hospital. The Fund had 21 scholarship students during the year, whilst in the United Provinces there is a Lady Assistant to the Inspector-General of Civil Hospitals (Dr. Shirin Commissariat). The Dufferin Fund in general adopts two main methods of providing medical assistance to the women of India; (a) by supplying officers of the Women's Medical Service, free of charge, to take medical charge; and (b) by grants in aid; and in the report under review Miss A. C. Scott, M.B., Chief Medical Officer, W. M. S., gives an encouraging report as the result of her visits of inspection to the main centres concerned, from which we take the following abstract.

Miss Scott reports that, with one or two exceptions, there is a decided improvement in the equipment of these hospitals, many have added to the accommodation for patients, chiefly in the provision of maternity beds, for it has been the experience lately that women are more ready to come into hospital for confinements than they were 10 or even 5 years ago. This steady increase of maternity cases as in-patients is of immense benefit, not only to the mothers and infants concerned but in providing practice for students, nurses and midwives in the training institutions which are invariably attached to Dufferin Hospitals. The reason for this increase is not far to seek; it is due partly to the breaking down of superstitions and ignorance about hospitals and partly to the spread of education in maternity and child-welfare work, by means of Baby Weeks, trained Health workers and other propaganda. There is also no doubt that the better nursing obtainable nowadays in our women's hospitals is appreciated by the mothers, many of whom return again and again for subsequent confinements.

Hospitals in the Provinces are still very poorly supported by both the local Governments and the public, though the hospitals are used freely by both officials and non-officials. In one case the hospital, to which a doctor of the Women's Medical Service is supplied, receives from the public only one-third of the amount which is monthly subscribed to the local infirmary for diseased and decrepit cows. In more than one city the Municipal body has reduced its grant to the women's hospital and in one case the local Government's grant has also been reduced.

There is a certain unfairness in the treatment of women's hospitals. Local bodies exact heavy rates, taxes for water, etc. These hospitals have to pay equally high customs and octroi duty as private individuals for drug and hospital necessities obtained from England, unprocurable in India, whereas the main Civil Hospital in the same town, being a Government institution, is exempt from these heavy items of expenditure. It will be a happy day for women's hospitals when legislators will vote money amounting to even half the annual expenditure of each.

An interesting resumé of the activities of the National Association (Countess of Dufferin's Fund) was given by Her Excellency Lady Irwin in presiding for the first time at a Council meeting in September, and this summarises the present position so admirably that we quote from it *in extenso*.

The National Association for supplying medical aid by women to the women of India is of long standing. It is now in its 41st year, and as you know, devotes its funds chiefly to the training of Indian women as doctors, but also gives grants to hospitals for women in different parts of India.

The Women's Medical Service is in its 12th year; it is paid for entirely from the Government of India subsidy, granted for this purpose to the Countess of Dufferin's Fund. This Service, from having a cadre of 25 officers has now one of 44, also a Training Reserve of 8 women graduates of Indian Universities; these graduates after 3 years' service in Women's Hospitals are granted United Kingdom scholarships with travelling expenses to England and back for the purpose of post-graduate study fitting them for full membership of the Women's Medical Service. I am much interested to hear that during this year for the first time one of the graduates from the Lady Hardinge Medical College, Delhi, has been appointed to the Women's Medical Service, and will be joining the College as Professor of Anatomy for the coming season.

The provision of a service of fully qualified medical women is the foundation and pivot of all work of the other funds.

In the first place, these highly qualified women are essential for the training of the students at the Lady Hardinge Medical College, Delhi, which students in their turn will take the place of their teachers in the Women's Medical Service, and continue to carry on the provision of medical aid by women to the women of India.

Secondly, they are essential to train the students in the Health Schools, to be Health Visitors and Maternity Supervisors, without whom the Maternity and Child Welfare work under the Lady Chelmsford All-India League could not be carried on.

And lastly, they are essential for the training of *dhais* and midwives so urgently needed for the rendering of adequate and skilled assistance to Indian women in child birth.

While speaking of the Chelmsford League, whose activities are mainly directed to the training of Health Visitors and propaganda, I should like to mention Lady Reading's last splendid gift to this work, which was to provide funds to build a new Health School in Delhi.

Hitherto students have had to reside in hired quarters and their instruction has been given in the various Municipal Welfare Centres in Delhi. The new School which bears Lady Reading's name, and to which is attached the model Rai Sahib Nanak Chand Infant Welfare Centre, will be ready for occupation by 12 selected students in October this year (1926).

On the propaganda side, "Baby Week," inaugurated by Lady Reading, is now a successful yearly event all over India, and a proposal is before you to-day to bring the management of this activity under the Executive Body of the Lady Chelmsford League, and therefore under this Council.

I have been asked to tell you that it is proposed to hold a Conference of Maternity and Child Welfare Workers and those interested in the movement in Delhi

early in February. It is felt that the time has come to report progress on this work which has now secured a firm footing in India. Six years have elapsed since those interested in this increasingly important subject had the opportunity to meet together to discuss the various methods employed and the difficulties encountered. An All-India meeting of the kind suggested will certainly be helpful to all concerned, and will enable us to lay our plans for further progress with more efficiency.

Much has been done but much remains to be done especially on the preventive side.

First and foremost there is the terrible scourge of tuberculosis, so especially active among the women and children in our large cities. Maternal and infant mortality are still very high as compared with other civilized countries. Women in villages and even in small towns are in the large majority of cases still unable to obtain any medical aid from women, even in the shape of a trained nurse or midwife. Separate and specialised relief for women provided by Municipal Bodies and District Committees is so far practically nil, and it is a fact that, though the purdah system is less strict than it used to be, there are few Indian women even to-day who will allow themselves to be treated by men doctors for any but trivial ailments.

I have only briefly referred to a few of the major evils that are still practically untouched, but I think even these show how vast is the field of work which lies before us, and how necessary it is for us all to continue our efforts and to combine in devising the best and most efficacious means to overcome these difficulties and varied problems.

The first report, that of the National Association, incorporates several subordinate reports of the chief institutions maintained by the Fund. The Lady Hardinge Medical College at Delhi is clearly faced with the universal hospital problem of India—how to keep down the number of patients to reasonable limits; the admissions to the obstetric and gynecological unit for example were 1,709 in 1926 as against 1,355 in the previous year. Miss G. P. Patel's work in the Medical and Pathology Departments of the College is singled out for appreciative notice. Dr. Keane of the Victoria Zenana Hospital, Delhi, reports difficulties in filling vacant posts on her staff owing to the low rates of pay sanctioned; also shortage of water supply during the hot weather. Dr. Houlton of the Lady Reading Hospital, Simla, reports a year of very strenuous work, with an ever increasing flow of out-patients and in-patients, but without any increase of staff; and similar reports of the great increase of work come from Dr. Bolton at Dera Ismail Khan, Dr. O'Brien Beadon at Madras, Dr. Kamalakar in Bombay, and from almost every centre concerned. "Good work under trying conditions"—an extract from the report by Dr. Murphy, of the Dufferin Hospital, Shikarpur—might well be taken to summarise these reports from different centres. Dr. Dodhi, from Hyderabad, Sind, reports that "the in-door maternity cases have trebled this year." It is abundantly clear that the policy of the Association is admirably suited to the needs of India. Further,—and this is a point of special importance—several Superintendents of Lady Dufferin Hospitals emphasise the special popularity of paying cabins for maternity patients from better class Indian families. Dr. Stapleton of Calcutta writes that extra beds have had to be put on the verandahs, and that an additional new ward is necessary. Also, throughout the report we are glad to see that special attention is being paid to the provision of suitable nurses' quarters, a matter which is all-important in this country. On the other hand there is general comment on the cutting down of local grants; on the parsimonious support given by the Indian community—who are very ready, however, to take advantage of the hospitals; on the need for better buildings and increased staff. A statement of the financial position of the Association shows investments of the total market value of Rs. 6,54,366 and trust funds to the value of Rs. 37,412; the total assets during the year—including income—were Rs. 8,47,802, and the

expenditure Rs. 1,26,182, with a closing balance of assets of Rs. 8,47,803 showing that the Fund, although not as well supported as it should be, is carefully administered. During the year a separate account was commenced for the Provident Fund for the W. M. S., India. Among the annexures to the report is a Seniority List of the Women's Medical Service which shows that there are 42 officers on the permanent cadre, with 2 temporary members, and 5 in the training reserve.

The second section of the report deals with the Victoria Memorial Scholarships' Fund. Here the general trend of the report is that progress is slow. "Miss Piggott in Sindh reports that only 200 women out of a possible 5,000 have been trained as *dhais*. This is disquieting, and the feeling of anxiety is not lessened by the realisation that the training of the remainder of the *dhais* is still a matter of great difficulty"—is a typical sentence from the report. Untrained *dhais* are trained chiefly in one of three ways: (a) by medical men and women; (b) by health visitors; and (c) by hospitals. The last is the most ideal method, whilst the first leaves something to be desired. A scheme has been started in Bengal for the training of *dhais* by private practitioners in the mofussil and the results of this experiment will be watched with interest. Training by health visitors is reported to be very satisfactory.

The difficulty about training in hospitals is the unwillingness of the pupils to leave their village homes for residence in hospitals in large centres of population. In the Punjab, as one would expect, ante-natal work has to be carried out chiefly in the homes of the people; "domiciliary midwifery, in view of the social customs and usages in force, must continue to be the main channel for conveying relief to the large majority of needy cases for some time to come." It is to be regretted that the expenditure from this Fund exceeded the income by Rs. 6,000, the total expenditure being Rs. 46,814 for the year. The Fund stands in need of philanthropic assistance if its admirable work is to continue.

The third section of the report deals with the Lady Chelmsford League for Maternity and Child Welfare. During the year the League supported or assisted four Health Schools, at Delhi, Lahore, Madras and Calcutta; the first named being the Lady Reading Health School. During the year the School moved into new and commodious quarters and is now a model of what it ought to be. The attendance at the School averages 35 to 40 expectant mothers daily, and the course offered to students is a very complete one, even vaccination and a study of child psychology being subjects in the curriculum. A special difficulty which appears to be encountered in North India is the lack of knowledge of English among the applicants for training at such a school, and classes have had to be held in the vernacular. On the other hand there are no textbooks in the vernacular, and lack of knowledge of English by the would-be students is generally an indication of an unsuitably low general level of knowledge. Well educated Indian girls appear to be backward in coming forward for training in midwifery. On the other hand it is reported from the Punjab that the education of girls is proceeding at a rapid pace, also that the school there has had ample financial help from the local Government. The Bengal centre is a very small one, with only three pupils, but Simla, Madras, and Bangalore report an influx of students. In connection with propaganda work the demand for publications, pamphlets, and posters is a steady one, though not vast in amount. The introduction of uniform record forms for maternity cases will help materially in connection with the collection of statistics, whilst the cinema is constantly in demand, and the exhibition of films illustrating maternity and child welfare work appears to be one of the best methods of instructing a rural population.

We have attempted to review this admirable report briefly, but in due measure; and we much regret that

the extreme pressure on our available space has previously held it up. The entire report is a record of steady and sustained progress. The report itself is also a great improvement on the reports for previous years: unlike them it gives the reader a real account of the work which is going on—work of tremendous importance for the future of India—instead of being a dry compilation of figures.

Correspondence.

TETANUS AND THE BONE-SETTER.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—The following case appears to be worthy of record in your columns.

A boy, A.B., aged 12 years, was brought to this dispensary on the evening of the 25th July, 1927, with a fracture of the internal condyle of the humerus, due to a fall from the parallel bars of a gymnastic apparatus whilst practising in a local school. The fracture was set and splinted, and all splints were discarded on the 14th August. On this date he could extend the arm completely, but could not completely flex the elbow. He was now put on to liniments and massage, and his relatives took him away. They were advised to consult a local practitioner in their neighbourhood, but did not do so. Instead, they took the boy to a local quack bone-setter.

The bone-setter claimed that the fracture had not been properly set, and advised that it be "re-set" and properly bandaged. With the permission of the relatives, he accordingly broke down the fracture, re-set the limb, and applied a bandage of date palm leaves and *Khol*—(a preparation of sesamum seeds, which is used in the form of cakes, and forms part of the diet of cows and buffaloes). On the third day the bone-setter applied a second dressing. Three days later, he advised the application of a hot tile, bandaged the limb tightly and applied a red hot tile to the elbow. The boy complained of intense pain, but was persuaded to undergo the treatment. He was sleepless for the whole night, and next morning cedema and blisters appeared on the hand and shoulder of the affected limb; these, he was told, were due to an insect bite.

That afternoon the patient removed the bandage for himself and was horrified to find the elbow very badly burnt. The bone-setter now advised the application of an infusion of certain leaves and prescribed an ointment; he then left the village, as he stated that he had urgent appointments elsewhere.

I saw the patient again first on the 28th September, 1927. By this time he had an ulcer 5 inches in length and 1½ inches in depth in its centre over the elbow. I dressed this and advised that he should be brought into my dispensary at Una. He was accordingly brought to hospital four days later.

On the 2nd October, 1927, typical tetanus developed, which set in gradually and by degrees. I wired for antitetanic serum from Bombay, applied hydrogen peroxide locally, and gave bromides and opium. Amputation was advised as the boy was in a critical condition, but this was refused by the relatives. Finally the serum arrived from Bombay and the patient was at once given 40 c.c. intramuscularly into the gluteal region, followed by a further similar dose the next day. Within fifteen days all symptoms of tetanus cleared up, and within a month the wound had healed. In his present condition the elbow is still flexed by scar tissue, (2nd November, 1927), and the hand in a condition of pronation. A plastic operation has been advised, but it is doubtful whether the relatives will consent.

The relatives were advised to lodge criminal proceedings against the bone-setter, but were unwilling to do so, as they put the blame on "destiny."

To what extent do Medical Councils and Registers help the qualified medical man in this country in connection with such cases?—Yours etc.,

G. M. MAHADEVIA, M.B., B.S.

UNA, KATHIAWAR.

24th December, 1927.

THE LABORATORY CONSULTANT.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—I beg to seek the support of your journal in giving my opinion in connection with laboratory diagnosis as carried out in Calcutta, and in certain mofussil towns in which I have practised. There is no question of the importance nowadays of laboratory aid in matters of diagnosis and prognosis, but in my opinion, in Calcutta at least—a city with regard to which I can now speak from some years' experience—the enthusiasm for laboratory diagnosis has attained a degree of perverted prominence which I have never observed in England, Scotland, or Ireland. The vast majority of general practitioners in Great Britain carry out the commoner laboratory tests for their patients themselves, and for doing so very few of them charge anything extra at all. Also in the big British hospitals either the physicians in charge—or more usually the clinical clerks or house physicians—carry out the simpler necessary tests, such as urine and stool examination, the differential leucocyte count, etc., and examinations of the sputum are carried out in less time than it would take to examine the larynx.

In Calcutta matters are apparently different, for there are a whole host of 'heart and lung specialists,' of biochemists and bacteriologists. The general practitioners in this city appear to have surrendered to the claims of the laboratory consultant. Surely it should not be beyond the powers and intelligence of the ordinary general practitioner to carry out the simple examinations required to find out whether his patient is suffering from malaria or kala-azar, from amœbic or bacillary dysentery; but apparently it is. He prefers to pin his faith to "therapeutic diagnosis," by which is meant that a given drug may or may not cure the patient, either by accident or because it is efficacious. Of course if the injection of drugs is the easiest road to money making, then, from a commercial point of view he is right. But it is not difficult to examine a specimen of urine for albumin and sugar, a specimen of sputum for the bacillus of tuberculosis, or a blood film for malaria parasites. Yet a general practitioner who will not hesitate to carry out a relatively difficult ophthalmoscopic examination will refer his patient for such laboratory methods of diagnosis to a "laboratory consultant." Again and again I have met with patients who had been referred to "research companies," when the necessary simple examinations could just as well have been carried out by the general practitioners concerned. Some of such reports have cost as much as Rs. 20 each—a sum which even well-to-do European patients might find it difficult to afford.

General practitioner as I am, I find myself constrained to protest against such a state of affairs. Where Dr. Napier and Major Chopra, I.M.S., have been striving to introduce simple and reliable tests suitable for the diagnosis of kala-azar by the general practitioner, there are laboratory specialists who will charge Rs. 10—or more for all that I know—to carry out the same tests. Why this cruelty to a community that is neither protected by a Health Insurance Act, nor by the provision of many charitable institutions?

The general practitioner in India should realise what it is that drives the ordinary Indian patient to the 'homœopathic,' the Ayurvedic and the Unani "systems" of treatment; it is their cheapness. But, with the assistance of the "laboratory consultant" we are making modern and scientific medicine too expensive for the ordinary Indian patient.

On the other hand, where there is real necessity for expert laboratory opinion, too often this is neglected

or overruled. To give an example I could quote two cases where lumbar puncture in the presence of almost certain meningitis was called for; the general practitioner in charge refused to have the operation carried out, because "it had never been done on any of his patients before." On another occasion analysis of the gastric contents was clearly called for, but this was refused, as it was a "messy affair." I have seen numerous cases of syphilis treated on clinical lines, without the Wassermann reaction being tested, and with no serological control as to the results of treatment or the indications for its discontinuance or otherwise. Recently a general practitioner who is familiar with Gram's stain, however, asked me if I could give him instructions as to how to prepare an autogenous vaccine—a line of work which would clearly increase his emoluments.

These matters need serious consideration by both the hospital authorities and private practitioners in Calcutta and in the big cities of India. Above all, and first and foremost, it appears to be necessary to drive home into the minds of medical students at college that the practice of medicine is in itself an art and science, and neither a money-making business, nor a house of charlatans and mystics.—Yours, etc.,

'G. P.'

CALCUTTA.

11th December, 1927.

(Note.—We do not publish anonymous contributions, except under exceptional circumstances, but 'G. P.'s' letter seems to warrant a breach of this rule, for he clearly speaks from personal experience, and has Indian, Edinburgh, and Dublin qualifications. Our sympathies lie entirely with him. If the general medical practitioner in India is not competent to diagnose a case of malaria by examination of blood films, a case of amœbic or bacillary dysentery by microscopical examination of the stools, a case of kala-azar by the simple serological tests, a case of plague, leprosy, or pulmonary tuberculosis by simple microscopical tests, then something is radically wrong. And that "something," if this be the case, is his medical education. To teach the practice of medicine to medical students in India it is necessary to recognise that tropical diseases are those which are most important in India, and not to model curricula for qualifying examinations upon British university syllabuses of twenty years ago. Finally, one would add that the laboratory worker himself, if he be worthy of his salt, will desire to be freed from such routine examinations and to have his time liberated for real research work.—EDITOR, I. M. G.)

INTRAVENOUS INJECTIONS OF SODIUM SALICYLATE.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—For the past two years I have been using the intravenous route for the administration of sodium salicylate in cases of rheumatic and myalgic affections with very good results. The relief of pain is rapid, the stiffness disappears much more quickly than by the oral route of administration; and the period spent in hospital is also cut short.

The strength which I use is 10 grains in 10 c.c. of water. Ten grains of sodium salicylate are dissolved in 10 c.c. of sterile water. This is then filtered into a test tube and boiled. The next step is to fill a 10 c.c. syringe, sterilise the skin over the median basilic vein, and to give the injection. I have never had any bad effects follow this line of treatment; also it has a certain diuretic action which helps to eliminate toxins.

I give two injections a week, and during the intervals the patient is on an alkaline mixture. During the acute period the diet is regulated to milk, rice conji, barley water, soda water, and so on; but once this period is over the patient is promptly put on to a very liberal and nourishing diet. Should the

patient be a "bed" case, a weekly purge is also administered.—Yours, etc.,

A. BAYLEY DE CASTRO,
Junior Medical Officer.

PORT BLAIR, ANDAMANS.
17th December, 1927.

RAILWAYS AND MALARIA.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—Professor A. Castiglioni in his article on "Malaria Control in Italy" in the *British Medical Journal* for the 13th August, 1927, has emphasised, amongst other measures, the necessity for the draining of possible breeding grounds of *Anopheles* larvae.

Travellers by railway must have frequently noticed the collections of stagnant water on both sides of the East Indian Railway from Burdwan downwards; on the Eastern Bengal Railway from Howrah upwards; and on the Bengal-Nagpur Railway; and almost along the whole of Northern Bihar along the railway there.

Railways are a most prolific source of *Anopheles* breeding places and of malaria of virulent type, and this applies equally to old established lines with borrow pits, badly designed culverts, and collections of standing water along the line, and to newly opened up sections where the engineering operations involved may frequently make conditions favourable for malaria where previously they were unfavourable. It is a common saying in Bengal that malaria spreads with the railways; that there is some truth in it is evidenced by seeing places which were once regarded as sanatoria now considered to be hotbeds of malaria after the introduction of railways into the areas concerned. The usual cause perhaps is the damming of the natural channels of drainage by railway embankments, these rendering the soil water-logged and giving rise to numerous sites suitable for *Anopheles* breeding places.

In order to remedy such conditions it seems to be absolutely essential that all new railway systems introduced should be compelled to allow of adequate natural drainage across the embankments made; and the same rule should also be applied to those railways already in existence. In Bengal at least, we are now accustomed to the saying "More railways, more malaria."—Yours, etc.,

K. C. GHOSE,
Assistant Surgeon.

MONGHYR.
8th January, 1928.

(Note.—"Malaria and railways" is an old standing subject of controversy in Bengal, if not in other parts of India also. There can be no doubt as to the crimes committed by bad alignment of railway arches and bridges—and especially culverts—which often create suitable *Anopheles* breeding places. Yet borrow pits and collections of standing water by the side of railways are often a less dangerous source of malaria than is usually supposed. On the other hand, malaria on Indian railways is a problem of special interest, since so many of the running staff are exposed to infection at night on trains, etc., who would not be so exposed if their duties were confined to the day time. That the railways of India are tackling their malaria problems seriously is shown by the recent advertisement for whole time malariologists for the four leading railways of India.—EDITOR, I. M. G.)

THE PERNICIOUS ANÆMIA OF PREGNANCY.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—On reading Dr. Margaret Balfour's very interesting article on this subject in your issue for September 1927, I am tempted to send you an account of

my own experience of this disease. I think that there is little doubt that the disease is becoming more prevalent; formerly cases of anæmia during pregnancy were rare, and were not accompanied by albuminuria and nephritis, but during the last year I have been called in to no less than four cases of profound anæmia in pregnancy, none of them associated with albuminuria or hepatic cirrhosis.

All four patients were young females of about the age of 20 years, belonging to fairly well-to-do and cultured Indian families, and not leading a strictly indoor or very sedentary life.

The first patient developed the symptoms in the 9th month, and had premature labour about 20 days before it was expected. She died on the 9th day after delivery. Various mixtures and injections of iron and arsenic were tried, without any success.

The second case showed marked symptoms of anæmia during the 7th month. Nothing could stem the progress of the disease, and she died undelivered about two months later.

The third case was noticed towards the end of the 9th month. A fortnight later she was delivered normally, and then steadily improved. Her health now, in the 3rd month after delivery, is very good. The child was none the worse for the maternal complaint.

The fourth case is a primipara, now 7 months pregnant. Her case is being anxiously watched. Everything possible has been done for her in the way of administration of drugs, but without benefit.

In all four cases, vomiting and a rapid pulse—about 120 per minute—were marked features. I have not seen diarrhoea associated with the condition; there is rather a tendency to marked constipation. The hæmoglobin index is about 20 per cent., whilst the blood picture is very atypical.

The incidence of this disease in India is so marked that one wonders why it has not attracted more attention.—Yours, etc.,

VENILAL N. MODI, M.B., B.S.

RAOPURA, LINDAPOLE, BARODA.
8th January, 1928.

MIGRAINE AND SUGGESTION.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—There is no doubt that migraine, in its severest forms, is one of the most terrible ailments that afflict the human body, and much interest has been aroused throughout the medical profession in all countries by the discussion on migraine at the Annual Meeting of the British Medical Association in 1926.

The interest has been continued and sustained by correspondence in the medical press on the subject of migraine—its causation and treatment. I do not think that I have missed any important part of the symposium of learned and acknowledged expert opinion. I gather that the treatment of this terrible affliction—like all Gaul in the time of Julius Cæsar—is divided into three parts:—

(a) The anti-proteid, anti-acid-producing, anti-acid-containing dietetic therapy.

(b) The anti-carbohydrate dietetic therapy.

(c) The combined medicinal and dietetic therapy; this part being sub-divided into what I may term, for the sake of brevity, $\frac{c}{2} + a$, and $\frac{c}{2} + b$. The first

part of (c) may be again and again divided in accordance with the tastes and fancy of the particular practitioner concerned, and his predilection for the older or newer drugs, from the salicylates to the latest coal-tar derivatives from the ex-enemy countries.

The factor of heredity is cited, and reference is made to the pathognomonic, customary, and mathematical periodicity of the symptoms in this fell disease. Causation—immediate, predisposing, and remote—is discussed, and theories are elaborated in a wealth of detail, from

faulty metabolism, endocrine disturbances, and hepato-gastric deficiencies in general, to idiosyncrasies and specific food-toxæmia. We are advised that, as many factors play their part in the etiology of this disease, treatment can only be carried out by well-organised and co-ordinated team work by the "close association of the physician, the neurologist, the ophthalmologist, the rhinologist, the dental surgeon, the pathologist, the biochemist, the psychologist, and other specialists,"—(the italics are mine). It is pointed out that change of climate and environment, relief from domestic cares, the stimulation of new scenes, and fresh interests in particular cases have seemed to prevent attacks, and this gives *some support* (*sic.*) to the usual view that migraine is essentially a neurosis.

A similar line of argument would relegate to the same category many diseases which are admittedly *not* neuroses. In the discussions to which I refer, attention was drawn to the nomenclature of the disease, to its symptomatology, its incidence with regard to age, sex, and heredity; to certain obvious exciting causes with special reference to eye-strain, vascular disturbances, and endocrine deficiencies; with further etiological considerations from the ophthalmic and other standpoints, and reference to the cranial, extracranial, and intracranial causes of headache in general, and of hemicrania in particular.

I do not propose to follow the arguments and opinions which have been put forward in detail. One writer gave it as his considered opinion that migraine—like such other explosive diseases as asthma, gout, epilepsy—resisted treatment because it is not a *disease*, but a *diathesis*, passed on from generation to generation. It is indeed extraordinary how many patients and how many doctors are reconciled to this policy of despair.

There is a patient living near me in Bombay, whose case I simply yearn to tackle. My reasons are not mercenary, as he is on my free list. He suffers from "paroxysmal hemicrania," and suffers often and terribly. He refuses treatment, because his mother suffered in exactly the same way, and he has obviously inherited his malady. Inherited liability in many cases is undoubtedly a powerful factor, but many cases originate in individuals *de novo*. Everything has a beginning somehow, somewhere, and somewhere. I am concerned at present, however, with the unsatisfactory state of the therapeutics of migraine and allied ailments.

We are overwhelmed with theories as to its causation, immediate and remote, from vaso-motor disturbances to pituitary enlargement, and from eye-strain to neurasthenic heredity. I need hardly say that I am in full agreement with many of the reasonable arguments advanced in the discussion, and with the view that the causation of migraine should be viewed from different standpoints, mental and psychical, whilst physical disturbances underlying the condition may also call for investigation and treatment. Whilst agreeing with all this, however, I am from time to time confronted with cases of migraine in which all such investigations have had no results, sometimes after a period of years and investigation by experts in many different countries. Am I to turn such patients down with the statement that I can do nothing for them? I can prescribe laxatives and purgatives, or salicylates and bromides: I can give antipyretic and analgesic drugs: I can confine them to strict dietaries—excluding every article of diet which, in their experience, may precipitate an attack: or I can order complete rest and a change of climate if their means will afford it; "but, as for cure, dear Sir, or Madam, the age of miracles is past. I do not know whether you have had endocrine or peptone therapy, and, though I am myself inclined to the vaso-motor as opposed to the gastro-hepatic theory, I do not propose to experiment with your organism by the exhibition of cerebral depressants or vaso-dilators with whose action and therapeutic activity I am not familiar. I must therefore advise you to proceed to Mentone, which has a relaxing climate and is nowadays comparatively free from Germans; or to Pontresina, which is exhilarating; anyhow you must depart

from this neighbourhood which you find unsuitable at the very onset of those premonitory symptoms with which your fourteen, eighteen, or twenty years of experience of the condition have doubtless made you familiar. If you cannot afford to take advantage of this advice, I can only recommend you to suffer as patiently as may be for a further period of years, until your time has come to depart for a better world. The approach of senility, or the menopause, may indeed relieve you in great measure; or, on the other hand, your symptoms may be aggravated by these conditions. I do not wish to be a Job's comforter, but your prospects are not bright. I regret that the present state of the law does not permit me to inaugurate a system of euthanasia on your particular behalf."

I have referred to inherited liability in these cases, but the factor of expectancy must not be ignored. I have at present a patient who has suffered for about twenty years from typical migraine, with but few remissions, the attacks occurring weekly or bi-weekly. One Monday morning I asked "How have you been during the week end?" The reply was "Quite all right, but then, you see, I am not due for an attack until Wednesday." Here we have a very powerful *malefic* auto-suggestion, which, being translated, means "I am due for an attack of migraine on Wednesday" and, sure enough, on Wednesday afternoon there arrives on time the aura characterised by visual or other customary phenomena, headache, alternately unilateral, nausea, vomiting, extreme depression, and exhaustion.

I have another patient who for five years suffered from daily paroxysmal unilateral headache. Under treatment by suggestion (in the waking state) he has been free from headache of any kind for the past eleven months, and is apparently cured, all other previous treatment having failed. As I write, there is seated in an armchair in my office a young educated Hindu, the son of a physician, who has consulted every possible medical opinion during the past fourteen years. A few months ago his father asked me if I could do anything for the son, who was in an alarming state of depression verging on melancholia. The attacks came on tri-weekly, lasted for some ten to twelve hours, were of the most severe type, with nausea and vomiting. When I first saw him he had just recovered from an attack which had left him with a condition of ptosis of the left eye, which rendered him more self-conscious than ever, and he was wearing dark coloured glasses to avoid observation. I have treated him entirely by suggestion, without any other line of treatment, for six months, and for two months he has been completely free of headache. The factor of fear, and of expectancy of an attack at a regularly recurring date is most important in many of such cases, and must be eliminated by suggestion.

It is difficult to dogmatise. Undoubtedly the causes of migraine are manifold; but experience and trial will teach one the best methods of therapy. A further example may suffice. Six months ago I was asked by a well-known Mahomedan lady to see a friend of hers, the wife of a *mullah*, who had been suffering continuously from headache and carache for six months—a condition which all lines of treatment tried had failed to cure. She was 55 years of age, and was ignorant of English, and I hesitated to undertake the case. On arrival at the house I found a piece of paper fastened to her hair above the left ear, which was the seat of the trouble, with a verse of the Koran inscribed upon it. I need hardly say that I made no attempt to interfere with this source of spiritual help, but proceeded to give suggestions of a curative nature in my halting Hindustani, having first satisfied myself by physical examination that there was no tumour, abscess, or other organic lesion to account for the trouble. A single sitting produced immediate relief from all symptoms of pain, and during the past six months there has been no recurrence.

One cannot account for the success of such suggestive therapy in any direct manner. In the above

case, however, it is clear that the earache was due to a chronic congestive state. The suggestions, which were accepted by the patient, gradually and teleologically relieved the excessive pressure of blood in the blood vessels of the ear, with immediate relief of the symptoms.

To those who disbelieve in the power of the mind, under mental suggestion, to influence the physical state of the body, I would recommend a study of the well-known works upon the emotions, which detail how fear causes blanching of the face, or anger a flushing of the facial and cervical capillaries. Apply this teaching to the cases of migraine—and they are many—which are amenable to suggestion therapy. "Suggestion is not a cure-all." But is that a logical reason for refusal to apply it in cases which appear to be suitable? Whatever the causation of migraine—whether due to vascular spasm, to endocrine disorder, or to local oedema—my experience is that the majority of such cases are readily amenable to suggestion therapy, when scientifically and methodically applied. Intelligent co-operation on the part of the patient, of course, is a *sine qua non*. Suggestion in such cases may be an empirical remedy, but it is an efficient one. Of course, it must be preceded by thorough physical examination, and mental and dietetic errors may require to be corrected. On the other hand, the psychical factor in such cases appears to be paramount. I know of one patient—a medical practitioner—who confesses to me that his attacks are often self-induced, and occur when he thinks over his liability to them; of another who suffered from migraine after apparently curing a patient suffering from the same complaint, apparently as the result of auto-suggestion.

Opinions with regard to mental therapy by suggestion are apt to proceed to one of two extremes; there is the type of medical man who shuts his eyes completely to its possibilities, and condemns the method without a trial; on the other hand, there is the type of practitioner who expects too much from it. *In medio tutissimus ibis*.—Yours, etc.,

W. NUNAN, M.D.,
Police Surgeon, Bombay.

BOMBAY.
10th November, 1927.

Service Notes.

APPOINTMENTS AND TRANSFERS.

The Viceroy and Governor-General has been pleased to make the following appointment on His Excellency's Personal Staff, with effect from the date specified:—

To be Honorary Surgeon.

Lt.-Col. F. P. Mackie, O.B.E., M.D., F.R.C.P., F.R.C.S., I.M.S., *vice* Lt.-Col. T. S. Novis, F.R.C.S., I.M.S., retired. Dated 21st November, 1927.

Lt.-Col. F. E. Wilson, I.M.S., an Agency Surgeon and Civil Surgeon, Quetta, is appointed to officiate as Residency Surgeon and Chief Medical Officer, Baluchistan, in addition to his own duties, with effect from the 1st January, 1928, and until further orders.

The services of Major M. G. Bhandari, I.M.S., are placed permanently at the disposal of the Government of Bombay, with effect from the 21st September, 1927, for employment in the Jail Department.

The services of Major K. B. Bharucha, I.M.S., are placed permanently at the disposal of the Government of Bihar and Orissa for employment in the Jail Department.

The services of Captain Som Dutt, M.C., I.M.S., are placed at the disposal of the Government of Bengal, temporarily, for employment in the Jail Department, with effect from the date on which he assumes charge of his duties in that Department.

Consequent on the appointment of Bt.-Col. S. R. Christophers, C.I.E., O.B.E., I.M.S., Director, Central Research Institute, Kasauli, as Member and Secretary of the Medical Research Institute Committee, Captain K. R. K. Tyenger, I.M.S., Assistant Director, Central Research Institute, is appointed to officiate as Director of the Institute with effect from the afternoon of the 3rd January, 1928.

To be Captains.

W. D. B. Read, 27th September, 1926, with seniority 16th May, 1926.

J. F. Hinksman, 27th September, 1926, with seniority 7th April, 1925.

J. L. Donnelly, 27th September, 1926, with seniority 21st March, 1925.

To be Lieutenants.

J. H. Clapp, 26th August, 1926, with seniority 15th June, 1924.

W. J. A. Coldstream, 27th September, 1926, with seniority 1st October, 1925.

T. A. Malone, 15th October, 1926, with seniority 2nd March, 1925.

(The notification in the *Gazette* of 11th March, 1927, in so far as it relates to these officers is cancelled.)

To be temporary Lieutenants with effect from the dates specified:—

Nanikram Chartsing Ramchandani. Dated 15th December, 1927.

Hasibul Hasan Khan. Dated 15th December, 1927.

Eruch Ardeshir Darukhanvala. Dated 16th December, 1927.

Michael Rodrigues. Dated 20th December, 1927.

LEAVE.

Major H. E. Shortt, M.B., I.M.S., an officer of the Medical Research Department on foreign service under the Indian Research Fund Association, is granted leave on average pay for 8 months with effect from the 1st April, 1928, or subsequent date on which he avails himself of it. His services are placed at the disposal of the Director-General, Indian Medical Service, with effect from the date on which he proceeds on leave.

PROMOTIONS.

Lieut.-Colonel to be Colonel.

Brevet-Colonel A. Spitteler, O.B.E., M.B., I.M.S., *vice* Colonel George Browne, D.S.O., M.B., I.M.S., retired. Dated 27th December, 1927.

Captains to be Majors.

P. Verdon. Dated 1st December, 1927.

J. M. Shah, M.B.E. Dated 17th December, 1927.

S. A. Phatak. Dated 23rd December, 1927.

Shridhar Atmaram Phatak. Dated 23rd December, 1927.

Reginald Arthur Waters. Dated 12th January, 1928.

RETIREMENTS.

Colonel A. Fenton, M.B., I.M.S., retires 25th November, 1927.

Colonel Robert Welland Knox, D.S.O., M.B., F.R.C.S. Dated 1st January, 1928.

Lt.-Col. L. T. R. Hutchinson, M.D., I.M.S., retires 19th November, 1927.

RESIGNATION.

Captain E. Kean, M.B., resigns his commission, 19th December, 1927.

NOTES.

THE THIRTY-THIRD CHEMISTS' EXHIBITION, LONDON.

The 33rd Chemists' Exhibition will take place, May 7th–11th, 1928, at the Holland Park Hall, London, W. The Exhibition was established in 1896, and has filled a very important need to the practising pharmacist in enabling him to see all the goods he sells and the

apparatus, etc., he uses in his profession, under one roof. The management is always delighted to welcome visitors from the Dominions and Colonies, and such gentlemen will be admitted on presentation of business card. The Exhibition is organised by the *British and Colonial Pharmacist* and is strictly confined to the Trade. The 1927 Exhibition was much the largest and most important yet held and the attendance exceeded all previous records, and the prospects for the coming events promise an even greater success.

RADIO-MALT.

THE necessity of vitamins in the diet was first clearly shown by Professor Gowland Hopkins of Cambridge in 1906—1912; and of the five vitamins at present known those most needed to be super-added to the normal dietary are vitamins A, B, and D, since natural food-stuffs are frequently lacking in them. Vitamine A in reality consists of two elements, vitamin A proper—which is a growth-promoting principle, and vitamin D, which is the anti-rachitic vitamin. The former also appears to help to maintain the bodily resistance against infections.

As the outcome of several years to experiment, the British Drug Houses, Ltd., London, have produced "Radio-Malt," a food accessory particularly rich in vitamins A and D. According to the claims of the manufacturers, the vitamin A in this is contained in a tasteless oil, now utilised for the first time as an accessory food. The vitamin D is derived by ultraviolet irradiation of its provitamin, i.e., ergosterol. These elements are combined in "Radio-Malt" with malt extract; the combination being free from cod-liver oil. This accessory food is especially indicated for administration to growing children, to weakly and tubercular children, and to invalids and convalescents. It is also of special value to the nursing mother, since both vitamins A and D are excreted in the maternal milk.

Radio-Malt is available from most chemists and druggists, and is put up in 1 lb. and 2 lb. jars. The Calcutta Agents are Henry S. Clark, 8/10, Waterloo Street, Calcutta.

A NEW VITAMIN PREPARATION.

THE problems of avitaminosis in India are very great. In the first instance religious customs debar certain castes from a dietary which contains a full vitamin content. In the second place climatic factors may affect the vitamin-content of what would otherwise be a satisfactory diet. The labouring and coolie class in India particularly, perhaps, suffer from vitamin defect. It is of interest therefore to know that Messrs. Smith, Stanistreet and Co., Calcutta, have recently produced a new vitamin accessory food—"Polyvalent Vitamine Compound, or Albegamin" intended especially for administration in labour forces, to coolies on tea gardens or in mines, who are below the due standard of health. This has been prepared as the result of the work of Mr. D. C. Sealy, who is associated with the firm, and who has had considerable experience of conditions on tea gardens. The chief constituents of the accessory food are stated to be germinated gram, calcium morrhuate, casein, glycerophosphates, the Indian molasses or *goor*, and sodium formate.

The experimental data on which the use of this preparation rest have been submitted to us, and are stated to have been briefly as follows:—

Rabbit No. 1.—Weight when caged, 770 gms. Fed on an ordinary cabbage diet.

Weight slowly increased to 990 gms. in 24 days.

Rabbit No. 2.—Weight when caged, 840 gms. Fed on cabbage diet, plus Polyvitamine Compound. Weight 24 days later, 1,080 gms.

Rabbit No. 3.—Weight when caged, 910 gms. Fed only on skimmed milk. Weight dropped to 740 gms. by the 19th day. Now put on to a diet of cabbage, plus Polyvalent Vitamin Compound. Weight increased to 1,020 gms. on the 24th day.

Rabbit No. 4.—Weight when caged 950 gms. Given only polished rice. Weight dropped to 650 gms. by the 22nd day, with definite neuritic symptoms. Now put on to a cabbage diet only. Weight increased to 810 gms. on the 31st day.

Rabbit No. 5.—Weight when caged, 740 gms. An attempt was made to feed this animal on Polyvalent Nutrient Compound only, but the animal disliked this diet, and its weight fell to 650 gms. on the 17th day. It was now given an ordinary cabbage diet, plus Polyvalent Nutrient Compound, and its weight increased to 1,020 gms. by the 24th day.

As far as these data go they would appear to show that the compound may be of considerable value in all conditions of malnutrition, and in convalescence after acute illness. The whole question of avitaminosis with regard to Indian populations is so vitally important that we are glad to see any attempt to put on the market a product that will give a rich and ready and easily assimilable supply of the whole group of vitamins. It only remains to add that the Polyvalent Vitamine Compound is put up in one lb. jars, and that it is on trial at present at the Eden Hospital, Calcutta.

RADIOGRAPHY FOR THE DENTIST.

A LITTLE brochure, which has recently been published by Messrs. Watson and Sons (Electro-Medical), Ltd., Sunic House, 43, Parker Street, Kingsway, London, W. C. 2, as their Bulletin No. 82, under the above title should prove of very great interest to dental surgeons in India. The brochure deals, *inter alia*, with the possibilities of dental radiography; the "Sunic" Mark II dental x-ray unit; which embodies several important new features, and which may be regarded as representing the high watermark of present dental x-ray manufacture—the complete price for the full outfit for direct current being £197-10-0; notes for the beginner on x-rays and their production; instructions with regard to technique for making dental radiographs; the various applications of x-rays to dentistry; and an account of accessories for dental radiography.

The whole brochure is excellently illustrated, and, in addition to price lists, etc., contains much useful information of a general character with regard to dental radiography. Its publication at least shows that British firms are quite as advanced as any others in this new and very important application of radiography.

Publishers' Notice.

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles will receive 25 reprints *gratis*, if asked for at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE Editor, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions, Advertisements, and Reprints should be addressed to THE PUBLISHERS, Messrs. Thacker, Spink & Co., P. O. Box No. 54, Calcutta.

Annual Subscription to "*The Indian Medical Gazette*," Rs. 16 including postage, in India. Rs. 18 including postage, abroad.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

Nothing Better

FRIGIDAIRE

ELECTRIC REFRIGERATOR

BEST

Frigidaire is the best domestic electric refrigerator because:—

The new metal cabinets are cheap.

Space for space and finish for finish they are the best value for the money on the market.

They are economical to run, the consumption of electric current being almost negligible.

They are practically inaudible in operation owing to the special spring suspended refrigerating unit.

They are all porcelain lined and elegantly finished in white, with bright metal fittings.

They require no cooling water and use no brine tanks.

These are only a few of the reasons why there are more Frigidaire Cabinets in use than all other types of domestic refrigerators put together.

Ask one of the 300,000 satisfied users about Frigidaire.

Write for particulars of Frigidaire domestic refrigerating cabinets, bottle coolers, milk coolers, ice makers, water coolers, etc.

THE WASSERMANN TEST IN INDIA. *

By R. B. LLOYD, M.A., M.B., B.Ch.,
 LEUTENANT-COLONEL, I.M.S.,

*Imperial Serologist and Professor of Serology,
 Calcutta School of Tropical Medicine.*

(Being a paper read at the Imperial Social Hygiene Congress held at the Caxton Hall, London, October 3rd to 7th, 1927.)

It is not necessary in these days to emphasise the importance of serological methods in the diagnosis and control of treatment of syphilis. The introduction of laboratory methods has led, as is universally accepted, to a greatly enhanced precision in our methods of dealing with the disease, both in its personal and public health aspects.

Some seven years ago I took charge of the office of Imperial Serologist, Calcutta. That laboratory, as part of its work, carries out Wassermann tests for the large majority of the Calcutta hospitals and for others in Bengal.

I thought possibly a brief report as to the value of the Wassermann test under Eastern conditions might be of interest to this Conference. As is well known, the Wassermann reaction is not a specific reaction in the bacteriological sense, and *a priori* some positive reactions in non-syphilitic conditions might be expected. In Europe the occasional positive reactions reported in non-syphilitic conditions have not been found at all to militate against its enormous value in diagnosis and control of treatment.

In India, where the bulk of the hospital population are illiterate, patients are usually unable to give anything approaching an accurate history as to when the malady commenced or its development. They seldom come to hospital early. When they do come, the characters of the primary lesion are frequently over-shadowed by subsequent septic changes which make opinions based on clinical examination extremely fallacious. (This is even more true in the case of female patients who will seldom come to hospital early unless troubled by some painful lesion. It is evident then that a Wassermann test, provided its specificity be as great in the East as in the West, is of even greater value in the routine management of such cases than it is under the ordinary conditions of Western practice.

Though I am not a clinician, it may be useful to mention a few general facts regarding syphilis in Bengal. The disease is extremely prevalent. In its appearance it is somewhat benign, and extensive destructive lesions are the exception. In many instances the primary sore is not characteristic, and may show no induration. Sores frequently assume a phagedænic form. Many are no doubt double infections. These sores are usually swarming with spirochætes. Secondary

* Published, with slight alterations, with full acknowledgements to, and by kind permission of the British Social Hygiene Council.

rashes are very little in evidence in skin clinics, and secondaries generally are insignificant or suppressed. Condylomata are however very common. The later lesions of syphilis are very noticeable in the wards of the Calcutta hospitals. For the most part these take the ordinary forms seen in the West. Grave cardiac lesions are frequent. Nervous lesions are prominent, especially a specific hemiplegia and transverse myelitis. Para-syphilitic conditions, as is well known, are very seldom seen. Many cases of anæmia in young men are met with with a positive Wassermann reaction. These do very well on anti-syphilitic treatment.

In regard to the specificity of the Wassermann reaction in the East it is clearly essential to examine the reaction in the common tropical disorders.

In endeavouring to arrive at a conclusion as to whether any non-syphilitic condition yields a positive Wassermann reaction we have first to examine a large series of such cases, and then to consider how many of the positive reactions may be attributed to co-existing syphilitic infection. In this an accurate history is very valuable. This is ordinarily quite unobtainable under Eastern conditions. Another method available is to examine the effect of anti-syphilitic treatment upon such positive reactions occurring in non-syphilitic conditions. A third method is to compare the percentage of positive reactions found in the clinical condition under investigation with the average syphilis rate of the community under examination. Wassermann surveys have not been made as yet in India on any extended scale, but from evidence of various kinds it is generally believed that the syphilis rate of the Calcutta hospital population is somewhere in the neighbourhood of 15 per cent. to 20 per cent. In the absence of accurate histories, the problem as to how far positive Wassermann reactions in non-syphilitic conditions are due to associated syphilis has therefore to be solved by a combination of methods two and three. A factor of very great importance in the elucidation of this problem is that the Wassermann test is not at present capable of standardisation into one fixed technique. The result of this is that results obtained by one method are not comparable with others, especially when wide variations in technique occur. An extreme instance of this is the use formerly of non-inactivated sera, which will yield many false positives.

Firstly, malaria. The question as to whether malaria will yield a positive reaction cannot perhaps be regarded as entirely settled. Personally I am strongly of opinion that, provided a Wassermann technique be used which conforms to modern requirements, the reaction will not be positive if the patient be free of syphilis. On the whole the literature indicates that this is so. There are however a few reports by competent workers using good methods which seem to show

that in a few persons subject to relapsing malaria normally possessing a negative Wassermann reaction the reaction may become positive during a malarial paroxysm. One cannot however altogether exclude the possibility that these patients had had syphilis previously and that the ensuing malarial attack exerted a provocative effect upon the negative blood reaction.

The practical aspect of this question is for the serologist to determine by the method which he himself uses if malaria gives a positive reaction. I am quite confident that the method used in my laboratory does not yield a positive result in malarial cases, whether febrile or otherwise.

It is unnecessary to say more than a word regarding yaws, which, though a common disease in many parts of the East, is rarely met with in Bengal. In generalised yaws the Wassermann reaction is positive. This is of no great importance clinically as yaws is easily recognised. Even if it were not, the error would not matter very much as the treatment is the same.

Leprosy is the one disease which is non-spirochætal in origin in which a high percentage of positive Wassermann reactions is found. In association with my colleague Dr. Muir of the Calcutta School of Tropical Medicine, I have made an extended enquiry into this question; comprising an examination of over a thousand cases. We first of all attempted to decide whether leprosy was a sequela of syphilis. We find that the Wassermann positive percentage in the early stages of both the dermal and neural types of leprosy is approximately 15 per cent., a figure which is within the estimated syphilis rate of the community. We conclude accordingly that syphilis is a factor of no importance in determining the incidence of leprosy. Twenty-one of these Wassermann-positive early cases of leprosy were subjected to anti-syphilitic treatment; and in every case the reaction became negative. We deduce from this that all these Wassermann positives were due to associated syphilis, and that therefore the leprosy process, at any rate in its early stages, does not produce reagins which will lead to fixation of complement. In the later stages of skin leprosy the matter is not quite so simple. Here we find a high proportion of positive Wassermann reactions (40 per cent. to 60 per cent.); a proportion which is two to three times the estimated syphilis rate in a disease which, in its earlier stages, shows no evidence of special association with syphilis. Thorough anti-syphilitic treatment of thirty-eight of these advanced cases abolished the positive Wassermann reaction in twenty-eight, approximately 75 per cent.

Presumably then three-quarters of these positive reactions in advanced cases are due to associated syphilis. How are we to explain these results? We have ample clinical evidence that the presence of syphilis has a disastrous effect on a case of leprosy. A mild case of leprosy when complicated with syphilis tends rapidly to assume

a grave form; and Dr. Muir and I are of opinion that this explains why the grave cases have a positive blood reaction in a far higher proportion than the early cases. In ten cases treated (25 per cent.), we found the Wassermann reaction resistant to anti-syphilitic treatment. Some of these are no doubt the so-called Wassermann-fast cases of syphilis. But we believe there is another factor, as there is evidence in leprosy of a peculiar serum change which may lead to non-specific reactions when what may be termed "ordinary" Wassermann techniques are employed. Dr. Muir is strongly of opinion that before instituting anti-leprotic treatment, the ground must be cleared by the removal of the co-existing syphilis if present; as otherwise such cases fail to respond properly to the leprosy-treatment. This view involves the serological examination of the blood of every leper before treatment is commenced. This is now done as a routine in Calcutta.

It is essential to devise then a serological test for syphilis adapted to the particular case of leprosy. What may be termed "ordinary" Wassermann methods, good in every other particular, will apparently always yield in leprosy, in addition to those positives caused by associated syphilis, some positives due to experimental factors. The reason for the latter is hard to determine, but it has been found by Kolmer that these non-syphilitic positives are eliminated by the use of his new Wassermann technique, an essential feature of which is the wide gap between the antigenic and anticomplementary doses of the antigen employed. It would seem therefore that the question as to whether leprosy will yield a positive Wassermann reaction is settled in the negative, provided syphilis be absent and a wide gap Wassermann technique be used.

As we find a preliminary serological test for syphilis to be essential before instituting anti-leprotic treatment, we should therefore use Kolmer's technique if the Wassermann test be used at all. We are now, however, experimenting with Kahn's flocculation reaction for this purpose; and up to the present the results have been satisfactory.

In connection with pregnancy, my experience has been that, excluding yaws and leprosy, a strongly positive Wassermann reaction occurring in this condition is certain evidence of the presence of syphilis. There is apparently a tendency to weakly positive reactions in pregnancy, apart altogether from syphilis. Some weakly positive reactions may, however, be connected with syphilis, which, as is known from clinical and experimental evidence, tends to assume a latent form in the pregnant patient, particularly apparently if the pregnancy and the syphilis commence concurrently. These weakly positive reactions would be reported by the laboratory as doubtful, and no harm would be done. It is interesting to note that Smith, using Kolmer's and other methods, found not a single positive reaction in ninety-four women in the last three weeks of gestation.

Presumably then in pregnancy as in leprosy the wide gap technique excludes what I may term non-specific positives. We know that there are changes in the blood in pregnancy, apart from disease. I have noticed a tendency to jellification of the pregnant serum on the addition of formalin, which is absent in normal sera. This raises again the question of the possible connection between the Wassermann reaction and the jellification by formalin.

The fact that a strongly positive Wassermann reaction occurring in a pregnant patient is, with the exception of leprosy and yaws, certain evidence of syphilis has naturally an immediate application to ante-natal work. It is also important in the investigation of diseases of unknown aetiology occurring during pregnancy. An important disease of this class, about which very little is known, is the anemia of pregnant women met with in Bengal. This is a very fatal disorder. In seven cases in which I examined the blood, the Wassermann reaction was strongly positive in five. Dr. Margaret Balfour, who is working on this disease in India, has followed up this idea, and in opening a discussion on the subject recently in Bombay she described the clinical and pathological features of the disease and stated:—"less than half of these patients' serums were positive to the Wassermann test." It would appear from this, however, that syphilis may be the basis of some of these cases.

An outstanding feature of tropical medical cases is the frequency of mixed infections. The serologist in the East would do well always to bear this in mind, and to adapt his Wassermann technique to this end; particularly in the matter of employing antigens with a wide gap between the antigenic and anticomplementary doses as recommended by Kolmer, when it is probable that less will be heard of positive Wassermann reactions in non-syphilitic conditions.

Another important application of the Wassermann test in India is in connection with blood transfusion. Some four years ago I introduced blood grouping tests into Calcutta, and blood transfusions are now frequently given for the conditions familiar in the West. This mode of treatment is also being extended to tropical conditions, e.g., kala-azar and certain of the anæmias. Leaving aside blood group determinations with which we are not concerned now, the blood of every proposed donor is examined in my laboratory by the Wassermann reaction. If the reaction is positive, the donor is of course rejected. If not positive, the question arises:—Is a negative Wassermann reaction proof of the absence of syphilis? Of course we know it is not. If it is not proof of the absence of syphilis, can we say that a person with a negative Wassermann reaction will not convey syphilis? No, we cannot say this either. The recipient must accept the risk of the communication of syphilis by transfusion. Every endeavour is made to reduce to a minimum the risk of infection by the use of an apparently absolutely healthy Wassermann-

negative donor. More than this is impossible. When time permits it is very important to perform the Wassermann test immediately before the donor is used, as although all donors are previously tested and known to be Wassermann-negative, the donor might have contracted syphilis subsequent to his first Wassermann test.

In general it may be said that with a good technique the diagnostic value of a positive Wassermann reaction is the same in the East as in the West, except in the case of yaws and leprosy, for which latter disease special arrangements are required.

With regard to the question as to which serological tests are the best for the diagnosis of syphilis in the East, at present I think the Wassermann test is the best. No doubt the technique is complicated, and experience is required in the interpretation of results. Yet in laboratories organised to this end, and with a trained staff performing Wassermann tests every day, this is a matter of no moment. The various precipitation tests are of course simpler to perform, and may have a great future before them. I see no reason at present to substitute them as a routine test for the Wassermann test, which, as performed in central laboratories, is admitted by all to be a weapon of astonishing precision.

From the point of view of organisation, arrangements in India are on the lines advocated by the Medical Research Council in their 1918 Report, i.e., Wassermann work is centralised in major laboratories where trained workers perform the test every day. Experienced physicians in India universally regard the Wassermann test as one of the sheet anchors in diagnosis. It is consequently essential that these tests be performed by a skilled staff, and be absolutely correct technically. The highest efficiency, combined with economy, is secured by the establishment of a few well-equipped laboratories in important centres. This is very convenient for the main hospitals and clinics in the cities. For the reduction of overhead charges and for the widest possible extension of the laboratory work, arrangements are required whereby the blood from patients in rural areas may reach the centre. In countries where centralised venereal clinics are available, the patient necessarily comes to the clinic for examination and treatment. There a specimen of blood is drawn and sent to the laboratory near by, which thus receives a fresh specimen, a very important point to the serologist. In India arrangements have not developed to this extent, and in the rural areas treatment is largely given locally. The physician in charge, when he wants Wassermann tests, has to send the specimens down to the laboratory by post or by special messenger. This works perfectly well for the three cold months in Bengal. During the hot months of the year the arrangement is not quite so satisfactory, though from practitioners prepared to take trouble, perfectly good specimens are frequently received in the hottest weather. The best plan in the hot weather is to send the tubes of blood in a box of sawdust impregnated with ice and salt.

Specimens of blood drawn in the hot weather if kept at air temperature become completely hæmolyzed in about two days, the final stage being a viscid almost chocolate brown fluid, the clot having gone completely into solution. Such specimens are very awkward to work with, and may set solid during inactivation. They are not necessarily highly anticomplementary, though many are so. Serum may also become highly anticomplementary if stale. This is no doubt due to bacterial contamination. Such sera are rejected. Every effort is made to obtain good specimens, fresh if possible, and in no case is a Wassermann result reported unless the controls are perfect. This rapid change in blood specimens in the hot weather is of no importance in the case of town work where the blood can quickly be put into the ice box, but it limits to some extent the application of laboratory work to persons in rural areas, as the blood specimens are apt to go wrong if left two or three days in the post. Blister fluid may no doubt be used for a Wassermann test instead of blood serum, but it is difficult to be sure how far the former represents the latter.

The question as to how elaborate pathological methods can be made applicable to the widest possible extent to persons living in rural areas is one of very great importance in large countries. It would seem that for those diseases requiring expert laboratory work and specialist treatment, the only solution is for the patient to come down to large centres. This is in fact in operation to-day at various special clinics of the Calcutta School of Tropical Medicine. This arrangement is satisfactory from every point of view, but it may eventually have the effect of unduly crowding these clinics. This subject is hardly my province, but I feel sure that in any scheme for the provision of venereal clinics in India the question as to how persons in rural areas are to receive the benefits of modern pathology and specialist treatment is one which merits very careful thought, both in its administrative and technical aspects. In England the bulk of the population is congregated in large towns. In India, on the other hand, over 90 per cent. of the people live in the villages. Venereal diseases are no doubt diseases of the town rather than of the country, and it would be very interesting to perform a Wassermann survey of a few Indian villages, selected to illustrate the prevalence of syphilis in rural areas and how it is affected by migration of the population from the towns. In this way we may hope to obtain some idea as to the magnitude and distribution of venereal diseases in India and the measures necessary to attack them.

GENITAL HYPOPLASIA IN WOMEN.

By P. C. DUTTA, M.B., F.R.C.S.(E.), D.G.O. (Dub.),
LIEUT., I.M.S.,

Indian Military Hospital, Lucknow.

HYPOPLASIA of the female genitalia is far more common than is generally recognised. It is often evidenced by the appearance of the individual, before examination or questioning. These

patients are of small stature, the limbs are child-like and the features are small and dull; the hair about the mons veneris is scanty, or it may even approach the male type, extending up to the umbilicus. The normal pad of fat which produces the prominence of the mons veneris is absent, so that the pubis feels very evident. These patients generally have contracted pelvises.

The history of the patient is often characteristic. It is generally of this nature. The menstruation has not appeared until very late, usually at the age of 16 or 17 in European countries, and about 14 or 15 in India. The menses are rather profuse, or it may be scanty, usually the latter. In this connection I would like to point out that menorrhagia may be associated with genital hypoplasia and deficient ovarian activity, often causing sterility. Recently I had the opportunity of seeing a case of this nature. The onset of the periods is often preceded by cramp-like pains, or there may be great pain during the whole of the menstrual period. Clots may occasionally be passed during menstruation. In older women, sterility is generally the rule.

Pathology. The causation of the pain was formerly believed to be due to an effort on the part of the uterus to expel the menstrual lochia, which it was unable to effect, owing to formation of clots, and tightness of the internal os.

This has been found to be untrue, because menstrual blood from such patients will not clot if kept in a test tube for weeks; though blood taken from the patient's veins will clot in a little under average time. All observers now agree that an antitryptic ferment removes thrombin from the menstrual blood and prevents clotting.

The cramp-like pains are due to premenstrual softening of the cervix, which takes place in a cervix where the amount of fibrous tissue is greatly in excess of the normal and in one where the cervix is long.

Symptomatology. The general aspect and development of the patient has been already described. The external appearance of the genitalia is characteristic. The normal pad of fat about the mons veneris is absent, and the pubic hairs are scanty. The labia majora are mere folds of skin, and there is no fat in them. The labia minora are usually small, but may be very obvious, due to the small size of the labia majora.

The vagina is long and tight, the fornices are flattened out, especially the anterior fornix, which therefore forms a poor receptaculum seminis. The cervix is long, conical, hard, with a pin-hole os, which however will admit a probe. The body and fundus of the uterus are small. The uterus is generally found in one of three positions, either acutely anteflexed, retroverted, or retroverted and retroposed associated with anteflexion. The probe often shows the length of the uterine canal to be normal, owing to the great comparative increase of the length of the cervix, which makes up for the lack of length of the body. The uterus may be displaced to

one or other side of the pelvis, suggesting previous inflammatory trouble. But this is unlikely in a virgin, who is not subject to tuberculous salpingitis. It has been shown to be due to intantilism of the pelvic connective tissue on one side, which causes lateral displacement of the uterus. The ovaries are generally high up and may be palpated with difficulty.

The following complications are often associated with genital hypoplasia. Dyspareunia is common, due to the small vaginal orifice. As the fornices are shallow and flattened, much of the semen is lost, so there is less chance of fertilisation. These two above mentioned factors lead to sterility. If the patient becomes pregnant there is a great tendency to miscarriage, but the prognosis is generally good for the next pregnancy. Labour is slightly premature, and the pains are poor, due to the lack of ovarian hormonal stimulus to the pelvic sympathetic. The babies are often small, and consequently there is not much disproportion. There is a distinct tendency for hyperflexion of the head. Superinvolution of the uterus is common.

Treatment. Whole gland ovarian extract should be administered. In Vienna they use a preparation known as Owowop, five tablets, after meals. Small doses (irritative dose) of X-rays to the ovaries have been used with success. This has been dropped of late owing to the danger of damaging the ovaries, but with proper dosage and in expert hands it is quite safe. Sitz baths, with carbon dioxide to stimulate the skin, are very useful. Instrumental interference with the endometrium causes ovarian stimulation, the mere rubbing of the endometrium with the sound being often sufficient. So dilatation of the cervix is very useful, (Loeb, 40 per cent. cure). The application of X-rays to the pituitary is much more satisfactory, and quite free from danger; the dose can be repeated in seven weeks. Where sterility persists in spite of the above treatment, the tubes should be tested with Rubin's apparatus.

DIFFICULTIES IN THE DIAGNOSIS OF FEVERS IN THE TROPICS.

By J. C. DE,

MAJOR, I.M.S.,

Police Surgeon, Calcutta.

In the tropics fevers are often puzzling as to their aetiology, and some fevers remain undiagnosed in spite of systematic examinations by clinical and laboratory methods.

The object of this paper is to deal with some fevers which may give rise to difficulties in their diagnosis.

Some of the fevers dealt with may be regarded as uncommon in occurrence.

It is possible that they occur more commonly than is usually supposed.

Some of them are of a mild type and are less likely to be met with in the wards of general hospitals, and more in the out-patient departments

and private practice. Investigation of such fevers by laboratory methods is therefore not likely to be sufficient.

If laboratory methods were as readily applicable as physical methods for the elucidation of fevers in the tropics, it would go a long way towards clearing up the aetiology of many obscure tropical fevers.

The value of laboratory methods in the diagnosis of tropical fevers is well known, but it might be mentioned that it is also important to determine correctly from clinical examination the kind of material which is appropriate for examination by laboratory methods for the particular disease, and the nature of the investigations required. Failure in this respect means also failure in respect of results from laboratory investigations.

This point will be illustrated in connection with one of the fevers dealt with in this paper.

For convenience of description the fevers described may be grouped as follows:—

GROUP I.—*Enteric-like fevers.*

GROUP II.—*Atypical enteric fevers.*

GROUP III.—*Other puzzling fevers.*

GROUP I.

Chart (A) is that of a Hindu male, aged 28, who was admitted into hospital on account of fever of three days' duration. The fever came on suddenly, accompanied by chill and headache. It followed a sub-continued course for three days after admission and a continued course for the rest of the week. It then became intermittent and finally normal after four more days.

The total duration of the fever was fifteen days.

During the acute stage of the disease the chief complaints were headache and frequency of movement of the bowels. The motions were chiefly liquid and yellow. During the stage the patient's expression was apathetic and his decubitus dorsal. His tongue was generally clean. Anorexia, sleeplessness, delirium, abdominal distension and a general toxic appearance, were absent. The pulse was not dicrotic, and the pulse-temperature ratio was normal. The internal organs showed no abnormal clinical change. The spleen was not enlarged.

Bacillus faecalis alkaligenes was isolated from his blood, cultured on the ninth day of illness.

A culture from his stool, made later during convalescence, showed an abnormally preponderant growth of *Bacillus faecalis alkaligenes*, being 85 per cent. of the total growth obtained.

Chart (B) is that of a Mahomedan male, aged 36, who was admitted on account of fever of four days' duration.

The fever came on gradually without any marked symptoms. His bowels had been constipated for several days prior to admission. The fever followed a continued course for twelve days after admission. It then became intermittent and finally normal after four more days. The total duration of the fever was twenty days. During the acute stage of the illness the following were the chief clinical features, (1) his decubitus was

dorsal, (2) expression apathetic, (3) sleeplessness very marked, (4) slight diffuse bronchitis present, (5) spleen enlarged one finger's breadth below the costal margin, (6) pulse-temperature ratio high. The important negative features were (1) tongue not dirty, (2) pulse not dicrotic, (3) abdominal distension, delirium and a general toxic appearance were absent.

Bacillus faecalis alkaligenes was isolated from his blood, cultured on the seventh day of illness. His bowels were inclined to be constipated throughout.

The two cases described resemble in several respects a fever of the typhoid group.

(3) Any marked signs of toxæmia were absent.

Chart (C) is that of a Mahomedan male, aged 26, who was admitted into hospital on account of fever which came on suddenly the day before.

He gave a history of having been knocked down by a cab five days previously which had caused an abrasion on the lower part of the left side of the chest. This injury was attended to in the out-patient department.

He appeared, at the time of admission, much prostrated and complained of a good deal of headache.

His tongue was coated on the dorsum and rhonchi were audible over the greater part of the

CHART - A

In the first case the continued type of pyrexia, earlier headache, later apathy, and looseness of the bowels were indicative in this direction.

In the second case the slow onset, a typically continued type of pyrexia of a duration more common to fevers of the enteric group, apathetic expression, sleeplessness, bronchitis, and the enlargement of the spleen were even more closely indicative in this direction.

The chief clinically important differences, in both cases, were

(1) The pulse-temperature ratio was either normal or high.

(2) The pulse did not show any dicrotic change.

chest. His spleen was not enlarged and there were no other special findings at the time.

The headache persisted from day to day and on the twelfth day of illness some stiffness of the neck was noticed. By the sixteenth day he had become stuporose and mildly delirious and sordes had appeared on the teeth, also jactitation of the upper extremities, some stiffness of the lower jaws, and a fairly marked Kernig's sign. The pulse-temperature ratio remained low throughout the greater part of the illness.

The fever showed a continued and a gradually ascending course during the first week after admission; it remained moderately high with

fluctuations during the second week; and became intermittent and finally normal during the third.

The total duration of the fever was twenty days.

Bacillus pyocyaneus was isolated from his blood cultured on the eighth day of illness, and from his cerebro-spinal fluid cultured on the sixteenth day of illness.

The cerebro-spinal fluid was under moderate pressure, faintly opalescent to the naked eye, showed a narrow ring of albumin with the cold nitric acid test, and microscopically a number of catarrhal cells and an actively motile bacillus.

Lumbar punctures were repeated as required to relieve nervous symptoms.

and partly open lips, showing dark brown lines of sordes on the front upper teeth, and twitching movements of the hands suggestive of idle picking at the bed clothes, made up a picture strikingly like that of one suffering from a severe attack of typhoid fever at a similar stage of the disease.

Chart (D) is that of a Hindu male, aged 28, who was admitted into hospital on account of fever. He had been suffering from periodical attacks of fever for about 2 to 3 months prior to admission.

The fever followed a sub-continuous course for eight days and then became normal.

His general health was poor, signs of diffuse bronchitis were present in the chest, and his spleen

ISOLATED FROM BLOOD

The Widal reaction of his blood serum carried out on the 21st day after the commencement of illness by Dreyers' standard method was negative to typhoid, and paratyphoid A and B bacilli in a dilution 1:25. The man made an uninterrupted recovery.

Apart from being an unusual type of septicaemia, the further interest of the case lies in the close resemblance existing between its course, clinical features, and type of pyrexia and that seen in typhoid fever.

During the second week of illness the patient, as he lay flat on his back with a heavy look on his face, muttering in delirium, with dry, cracked,

was enlarged two finger-breadths below the costal margin, rounded and soft.

No malarial parasite was found in blood films of his peripheral blood, and no tubercle bacilli in his sputa.

The blood count showed the white cells reduced to 3,000 per c.mm. of blood, and the differential count was as follows:—

Polymorphonuclears	..	54 per cent.
Small mononuclears	..	38
Large mononuclears	..	8
Eosinophiles	..	0

The formol-gel test of his blood serum was (±)

Herpetomonad flagellates were isolated from his blood on special culture.

While dealing with these continued type of fevers, it may be appropriate to indicate here other fevers of the same type which, on account of their indefinite clinical features, are apt to be diagnosed, though incorrectly, on the basis of a predominant clinical sign, as malaria, bronchitis, influenza, etc., or in the absence of such signs styled "pyrexias of uncertain origin," a term which is in itself obviously an inaccurate one.

Chart (E) is that of Mahomedan male, aged 26, who was admitted into hospital on account of fever which had come on the previous day with

Exhibition of quinine failed to produce any effect on the temperature.

A culture from his blood, made on the 8th day of illness, proved sterile, and a culture from his urine made on the 12th day of illness yielded a heavy pure growth of *Streptococcus viridans*. His sputum was collected on the 12th day of illness. It was muco-purulent in character. No tubercle bacilli were found in films made from this collection.

The signs of diffuse bronchial catarrh persisted after the temperature had returned to normal, and another sample of sputum was collected and examined and this time a number of tubercle bacilli

CHART - C

rigor. He had served for about seven years as a police constable. He had occasional attacks of fever which were quickly recovered from, but he had never felt ill enough to go into hospital.

His general health was fair. His spleen was enlarged two finger-breadths and liver one finger-breadth below the costal margin. The heart was normal, the lungs showed signs of diffuse bronchitis and prolongation of expiration.

Cough was not complained of nor noticeable. The fever, after fluctuating for two days, settled down to a continued course for seven days and fell to normal by lysis on the 12th day of illness. The pulse-temperature ratio during the febrile period remained low and the frequency of the respirations high.

were found in the smears made and were found again in fresh samples taken two days later.

The patient remained for some time afterwards in hospital, and 27 days after admission coughed up a little blood. Soon afterwards signs indicative of breaking down were distinguishable at the apex of the right lung.

The manifestation of pulmonary tuberculosis as an acute febrile illness of the typhoid type is by no means uncommon. The clinical resemblance of fevers of the typhoid group is remarkably close. In the case quoted above the diagnosis remained doubtful until tubercle bacilli were found in the sputum. I have come across several cases of this kind. In some cases the presence of a slight blood tinge in the sputum

drew attention to their possibly tubercular origin. In others no indications in this direction were available from the

characters of the sputum. Tubercle bacilli have been found in sputa entirely mucoid in character. In some cases where there was hardly any ex-

CHART - F

CHART - G

pectoration the examination of whatever sputum was available after giving stimulating expectorants revealed the presence of tubercle bacilli. In many of these cases both the history and signs in the chest were of a very indefinite character. These findings, I think, show the importance of excluding by examination of the sputum the possible tubercular origin of acute fevers of the typhoid type where the diagnosis rests on clinical grounds, and the help that may be received in this direction from the administration of stimulant expectorants.

Group II.

Whilst fevers of the typhoid group are usually characterised by continuous fever over a long continued period, it is important not to forget the existence of mild and abortive forms of typhoid.

Charts F and G will show how easily the fevers showed therein might be ignored, as not of

Group III.

Coming now to other fevers of a puzzling nature, the following cases are of interest:—

Chart H is that of a Hindu male, aged 36, who was admitted into hospital on account of fever of three days' duration.

On examination signs of congestion over the posterior aspect of the upper lobe of the right lung were noted and in a few days' time signs of consolidation were marked over this area. A total white cell count showed a leucocytosis of 16,250 per c.mm. of blood. The fever maintained a continued course for seven days after admission and then touched normal without any marked critical signs. It rose again, however, and maintained a steady continuous course for the next five days.

As the temperature remained up till the 13th

CHART — H

any material consequence, or diagnosed as seven day fever, bronchitis, etc.

The importance of a correct diagnosis lies not only with regard to prevention of spread of infection from an undetected typhoid convalescent acting as a carrier, but also in guarding the individual from a relapse. I have known relapses to follow through too early a resumption of ordinary diet in a person convalescent after typhoid fever, in whom the true nature of the first attack was not realized. Such relapses are usually more severe than the original attack and may even prove fatal.

day of illness and there was no sign of involvement of fresh areas of the lungs, a blood culture was made and the pneumococcus was isolated from the blood. The temperature finally became normal on the 21st day of illness.

The pneumococcus, in the majority of cases of pneumonia, may be isolated from the blood during the first few days of the disease, but the persistence of the organism in the blood stream in the later stage of the disease seems to show that in this case it was more a systemic than a local invasion which was concerned in maintaining the fever for over twenty days.

Chart I is that of a Hindu male, aged 26, who was admitted into hospital with a temperature of 103.4°F. The fever had come on suddenly the previous afternoon with rigor. Marked increase of polymorphonuclear leucocytes was noted on blood films made from his peripheral blood, whilst these were being examined for malaria. Examination of the chest showed a somewhat impaired percussion note, diminished breath sounds, and a few crepitations over the right subscapular region of the chest. It was thought that these signs indicated an impending pneumonia. There was however no cough, no expectoration, and pain over the part. After a week the lung

from culture of his blood taken on this day. The streptococcus was unfortunately not typed.

This case presents several points of interest in connection with its differential diagnosis. The course of the fever was marked by considerable fluctuations of temperature. The rises and falls of temperature were accompanied by rigor and sweating respectively, but not always. These made it appear at first as if the fever was due to malaria but quinine failed to stop the rises of temperature. Later, on account of signs in the right lung, impending pneumonia was thought of as probable, but as the fever progressed the lung signs receded instead of developing. Later still,

CHART - I

note and the breath sounds in this region were still impaired; the adventitious sounds had disappeared but a few rhonchi could be heard in the left lung. The spleen was now slightly enlarged and soft. Slight dilatation of the heart was present and a soft systolic bruit could be heard at the apex. The pulse was soft, rapid, and compressible. His mental condition, which was at first clear, now became stuporose. His temperature, which had been falling during the preceding 2 days, rose again to high levels.

On the 10th day of illness he passed a few liquid motions tinged with blood, such as are seen in typhoid fever.

A pure growth of a streptococcus was obtained

when the temperature became high and sustained, the mental condition dull, and blood appearing in the stools a suspicion of typhoid fever was aroused. But the type of temperature was inconsistent with that of typhoid fever and it fell to normal by crisis on the 12th day of illness.

No definite focus of infection from which the invasion of the blood stream by streptococci had taken place was found, unless it was a deep seated focus in the right lung.

There is another type of infection which gives rise to fever not readily distinguishable by its clinical features, and which may be mistaken for malaria, of which the following case is an instance.

Chart J is that of a Mahomedan male, aged 35, who was admitted into hospital on account of fever which had started suddenly with rigor, 2 days previously.

On examination a few scattered râles and

rhonchi were noted in both lungs, the spleen was not enlarged, and the tongue was fairly clean.

No malarial parasite was found in his peripheral blood films. The total white cell count was 11,600, per c.mm. of blood. *B. coli* was isolated

CHART - J

CHART - K

botanical source of this drug and his suggestion was confirmed by the researches of Falconer who visited Kashmir and found that *Aplotaxis lappa* growing there was undoubtedly *Auclandia costus*, now known as *Saussurea lappa*. It is a tall, very stout herb, with annual stem, heart shaped leaves and thick perennial roots which are dug up in the months of September and October. It grows chiefly on the moist and open slopes of the Himalayas, especially those surrounding the valley of Kashmir and adjacent ranges, at a height of 2,000 to 13,000 feet above the sea level. The best root is grown over an altitude of 9,000 to 13,000 feet. The root occurs in crooked twisted pieces about 3 inches long, $\frac{1}{2}$ to 1 inch in diameter; it is collected and exported to China in large quantities without any further preparation. It is also shipped to the Red Sea and Persian Gulf. The root fetches a very good price, as much as four hundred rupees (£25) being paid for a maund (80 lb.). In China it is chiefly used as an incense, as a spice, and medicinally as a powerful aromatic stimulant, carminative, antispasmodic and in the form of an ointment for external application. It is a very old remedy of the Hindu medicine and has been described in the *Nighantus* as a remedy for cough, asthma, fever, dyspepsia and skin diseases. The Arabian medical writers describe it as a diuretic and anthelmintic, and use it in the treatment of quartan fever and leprosy.

Chemical Composition and Pharmacological Action of *Saussurea lappa*.

The chemical composition and the pharmacological action of the drug have been worked out and the details will be published shortly. It will suffice here to say that the chief active constituents isolated from the root are an essential oil which forms 0.5 per cent. of the root, traces of an alkaloid, a bitter substance of glucosidic nature, and a resin. The most important of these from a medicinal point of view is the essential oil, though the alkaloid and the glucoside may undoubtedly help. The essential oil has a strong, aromatic, fragrant and penetrating odour. It is rapidly absorbed and is excreted into the lungs, and during its excretion produces not only relaxation of the bronchial muscles but also has an expectorant action. An alcoholic extract prepared from the root which contains most of the active principles has been used for therapeutic trials and all our cases in the present series were treated with it.

Causation of Asthma.

In order to appreciate the value of this remedy in the treatment of asthma it will be necessary to say a few words about the causation of this symptom-complex. In previous papers published by the author in collaboration with Lt.-Col. H. W. Acton, I.M.S., on the causation and treatment of asthma, it was

pointed out that three factors are concerned in producing the paroxysms. Firstly there are certain toxic bases which when entering into the circulation produce constriction of the bronchial muscles and turgescence of the mucous membrane. These bases may be of extrinsic origin, e.g., emanations from animals, pollens of various grains, etc., or of intrinsic origin, that is to say produced in the body itself, e.g., toxins produced by bacterial or other infections in the respiratory and gastrointestinal tracts (*E. histolytica* infection), or elsewhere in the body. In the latter group are also included some of the common food-stuffs which bring about asthmatic attacks. It is a well-known fact that two classes of substances whose chemical composition we know give rise to bronchial constriction. (1) Bases formed from disintegration of the protein molecules, e.g., amines and allied bodies which act through the sympathetic. These may be volatile substances, such as trimethyl amines (emanations from animals probably belong to this class), or non-volatile, such as histamine. (2) Alkaloids such as pilocarpine, physostigmine, arecoline, etc., which act through the vagus.

The second important factor in asthma is the defensive mechanism of the body against these poisonous bases. This consists in increase in the leucocytes, mainly in the eosinophiles which may be as high as 80 to 90 per cent. Eosinophilia is an indication of the circulation of these poisonous bases in the blood-stream and is often considered to be a sign of irritation of the vagus. The detoxicating action of the liver is a very important factor in the food poisoning group when the poisons are coming directly to this organ from the intestine. The activity of the endocrine organs must necessarily play a very important part. If the liver is functioning properly and the action of the endocrine glands is normal, the poisons that are coming into the system are controlled by this combined defensive mechanism. When this mechanism breaks down, it is only then that these bases can exert their baneful effects on the bronchi and produce asthma as well as give rise to eosinophilia. Acton and Chopra have shown that epinephrine in 1 : 1,000,000 dilution can prevent the contraction of the isolated guinea-pig uterus caused by a 1 : 100,000 dilution of such a strong base as hordenine, and probably similar phenomena occur in the body.

The third factor to be considered is the tonus of nerves that receive the stimulus of the poison. The tone or equilibrium in the body is kept up by the protoplasm of the cell, the most primitive tone, and secondly by the individual tone of the vagus and sympathetic. In this way an elaborate system of balance is kept up which is not easy to upset except in disease. Variations in tone may occur in either of the two systems, as hypo- or as a hyper-activity. Bauer has observed that

normally during sleep there is a physiological vagotonia. This hyper-activity of the vagus is shown by contraction of the pupils, slowing of the pulse, and a tendency to perspire. This fact probably partly explains why labour pains and attacks of asthma usually occur during the night. Another reason is that during sleep waste products are not eliminated by the urine and faeces and moreover after the main evening meal the amino-acids, etc., produced by the digestion of proteins reach the large intestines 4 to 6 hours later, where they are further broken down by the bacteria into poisonous bases. These two factors probably account for the attacks which occur about 3 o'clock in the morning. In view of these facts, the attempt has been made to classify asthmatic patients according to the predominance of the vagus or sympathetic systems, but in practice, while one does sometimes come across cases of simple vagotonia and sympathicotonia, by far the largest majority of patients belong to the type of hyper-excitability of both the systems. Thus in a case of sensitiveness to a particular food the repeated attacks render the patient more liable to attacks of bronchitis, and this in its turn leads to the development of sensitiveness towards the causative bacteria. Again, irritation by vagotonia produces asthma and ill-health, then perhaps sensitiveness develops towards some food-stuffs.

Saussurea lappa in the Treatment of Asthma.

It will be seen, therefore, that not only do different cases of asthma react differently to different toxins which may gain access to the circulation, but their reactions to different remedial measures also differs. This makes the treatment of this symptom-complex a difficult matter. Every case should be treated on its own merits. The cause giving rise to attacks should be discovered and remedied, but this often is no easy matter and may take a considerable time. In this connection the reader is referred to the papers by Acton and Chopra (1923 and 1925) in the *Indian Medical Gazette*. Without due attention to it, however, permanent cure cannot be expected and eradication of the causal factor should always be kept in view in the treatment of this condition. The first consideration, however, in most cases is the symptomatic treatment, so that while the causal factors are being investigated the patient is kept free from paroxysms. During the last few years we have had the opportunity of studying a large number of cases of asthma and have tabulated some of our results in Table I.

It will be seen that a large number of asthma patients one meets with in this country, although suffering from the hyper-excitability of both the systems, show a greater degree of irritation of the vagus than of the sympathetic. The action of the vagus is increased owing to certain causes,

not only producing spasm of the bronchial musculature but also vaso-dilatation of the bronchial mucosa, which give rise to attacks of asthma. These effects can be relieved by atropine and to lesser degree by inhalation of fumes of stramonium, tobacco leaves, etc., which diminish the vagus action, or adrenaline, ephedrine, etc., which stimulate the antagonistic action of the sympathetic. In the vagal predominance adrenaline has only a slight and evanescent effect in overcoming bronchial constriction caused by the action of these bases acting on the vagus. Five minimum doses in these cases produce a high rise of blood pressure and irregular action of the heart. For this reason adrenaline is not suitable for these individuals and we have to look for something which will act on the vagal mechanism. The disadvantage of atropine and allied substances is that although they depress the terminations of the vagi, they have little effect in relieving the turgescence of the mucosa. In fact on account of their tendency to decrease the secretions, they make the sputum more viscid and difficult to expectorate. That is the reason why they are often combined with drugs like potassium iodide which render the sputum more fluid and which usually form a part of asthma mixtures.

Following up the broncho-dilator and marked expectorant action produced by *Saussurea lappa* in animal experiments, during the last few years we have given an extensive trial to the alcoholic extract prepared from the root in the treatment of bronchial asthma with very satisfactory results. This drug not only has a depressant effect on the vagal tone, but the essential oil during its excretion through the bronchi serves two important purposes. Firstly it produces relaxation of the involuntary muscle fibres of the bronchioles, and secondly it relieves the congestion of the bronchial mucosa by its well marked expectorant properties and its liquifying action on the tenacious sputum which occurs during the paroxysms and tends further to block the already narrowed air passages. The phlegm thus becomes loosened, is easily expectorated, the respiratory passages are cleared, and the attack is relieved. There is yet another action which comes into play and that is the reflex inhibition of the respiratory centre produced by the drug. We have already pointed out that the essential oil present in the root has a very strong, penetrating, and persistent odour and taste, and when the extract is taken by the mouth it relieves the bronchial spasm reflexly through the nerves of the upper portions of the respiratory and the digestive tracts. Besides this the drug has been shown to have a depressant action on the central nervous system, particularly on the algæic areas of the brain, which further helps in relieving the spasm. These factors undoubtedly account for the rapid effect produced by the

drug in cutting short the paroxysms and stopping further attacks when the extract is being administered. The strong smell and taste of the drug though advantageous in one way have disadvantages also. There are some patients, though fortunately a very small minority, who cannot take the drug on this account and if it is forced on them they vomit it. I have heard some of these patients say that they would much rather have the asthma than the drug.

The extract is administered either by itself in a little water or in form of a mixture such as the following:—

℞			
Potassium iodide or potassium			
bromide	gr. v to x.	
Tincture of belladonna	m. iii to v.	
Borax	gr. ii.	
Extract <i>S. lappa</i> liq.	drs. $\frac{1}{2}$ to 2	
Spr. chloroform	m. x.	
Aquam	oz. i.	

Though it is better to give the extract by itself when the drug is being administered to cut short a paroxysm, we prefer to prescribe the mixture when the administration has to be continued for some time to prevent further recurrence of the attacks, while the causal factors are being investigated and remedied. The drug has no cumulative action, so that it can be continued for long periods without harm, and it does not cause tolerance so that the dose has not to be increased. It is, however, desirable to give the mixture for ten days or a fortnight and then stop it to see if the attacks recur. In many cases where the paroxysms are merely produced by irritation through some temporary and not a deep seated cause, the extract combined with general treatment cures the patient for months or years and the attacks do not recur till these factors operate again. The patient is generally advised to take the mixture 3 or 4 times a day and keep a dose by his side when he goes to bed at night. This should be taken immediately when the premonitions of an attack are felt; the paroxysm is usually aborted and the patient can go to sleep again. The disturbance of sleep produced is comparatively much less than if an injection of adrenaline has to be taken or a powder has to be ignited and fumes inhaled. In fact the marked depressant action on the central nervous system which it possesses makes the patient quickly fall into a deep and sound sleep.

The series of cases tabulated includes many interesting cases. It includes a number of patients who were so bad that they could not sleep without an injection of adrenaline every night. Administration of the extract in 2 to 4 drachm doses stopped the recurrence of paroxysms. Another patient, a European Railway Officer, could not lie on his back at

night as the paroxysm would start as soon as he was in the recumbent posture; he had in consequence to sleep in a deck chair for three months. Regular use of the extract combined with exclusion of articles of dietary to which he was sensitive completely relieved him and he has now been free for nearly three years. Another case in this series was an Anglo-Indian employed in the Telegraph Workshops who had a history of previous attacks and who started very severe paroxysms when he was transferred to a branch where he had to work among acid fumes. Even on transfer back from this section the attacks continued for months, and when he came to the outpatient department he informed me that he had not slept for three weeks. The extract gave him immediate relief and with due care regarding protection from irritating fumes, etc., he has been quite free from attacks. He keeps the extract as a standby and takes it when he has a feeling of constriction in the chest or some other premonition of the attack after working in an unsatisfactory atmosphere. Many other similar cases may be cited from our series. Case No. 34 is of interest because she was one of those patients who could not take the extract of *kuth* root on account of the nausea it is liable to produce. She came into the hospital with a severe attack and injections of adrenaline, morphine and atropine ephedrine and asthma mixture by the mouth, inhalations of amyl nitrite and other remedies were tried without success. The attack lasted for four days and was eventually got under control by subcutaneous injection of gr. $\frac{1}{100}$ to $\frac{1}{50}$ of trinitrin. The drug failed in those cases where the causal factor was very potent, such as patients with a very high degree of eosinophilia, an indication that strong toxic bases were being absorbed into the circulation from some focus, or with such factors as a lesion in the nose, enlarged glands in the chest, or pathological changes in the gastrointestinal tract. Even in these patients there was some relief, though it was of a temporary nature.

Summary and Conclusions.

Saussurea lappa (*Kuth* root) has a remarkable effect in controlling the paroxysms of bronchial asthma. It cuts short the attacks and appears to have a marked and lasting effect, not only on the neuro-muscular apparatus of the bronchioles, but at the same time it relieves the turgescence of the bronchial mucosa by its well marked expectorant action. The tenacious sputum becomes liquified, is loosened and is easily expectorated, thus clearing the respiratory passages and preventing recurrence of attacks. It should be clearly understood, however, that although the paroxysms can be controlled in most cases the drug does not produce a permanent cure unless the causal factors are carefully investigated and removed.

The antispasmodic effect of this drug is mainly due to the powerful essential oil contained in the root which acts (1) reflexly, and (2) relaxes the bronchial musculature during its excretion. The drug further has a depressing action on the central nervous system, particularly on the algæic areas, and a stimulant action on the heart.

I am greatly indebted to Drs. J. C. Gupta, N. K. Basu and K. Venkatachalam Pillay for the trouble they have taken in helping me to analyse the cases given in the table.

AN OUTBREAK OF THE EPIDEMIC DROPSY TYPE OF BERIBERI IN ALLAHABAD, 1927.

By R. N. BANERJI, M.B., B.S.,
Allahabad.

THE epidemic started about the middle of January, 1927; it reached its height in February and March and gradually passed away by the end of April, 1927.

Nearly 200 cases occurred scattered all over the town. Out of a total of about 500 Bengalee families about 100 families were affected.

The cases were restricted almost wholly to the Bengalee population. There were only 6 cases among the non-Bengalees, one in a Bengalee Muhammadan, one in a hill-man employed under a Bengalee clerk and sharing food with his master; and four among the Indian Christians. There were no cases among the Europeans or the U. P. Muhammadans. The diets of the Bengalee Muhammadans and native Christians, as also their habits were like those of the Bengalee Hindus.

The age incidence was between 4 and 60 years.

The incidence among females was much greater than among males (nearly thrice).

Breast-fed babies escaped entirely.

There were many cases among the Hindu widows who did not take fish or meat, but otherwise their diet was the same as that of the rest of the population.

Symptoms.—Nearly all the cases started with gastro-intestinal irritation, diarrhoea, anorexia, etc.

The pyrexia was of varying duration—with a remittent or intermittent type of temperature; the range of temperature was 99 to 101 or 102°F.

The œdema was confined chiefly to the legs and feet. In some cases it involved the arms, face, and hands. The œdema was more marked in the evening, decreasing after the night's rest.

There was no true neuritis, no pain, no sensory disturbances.

There were no rash or skin eruptions, but the skin over the legs turned purple towards the evening.

Serious cardiac involvement was not frequent; there was dyspnoea in many cases and cardiac dilatation with murmurs in only a few cases.

There was anæmia and general running down in health.

There were no hæmorrhagic signs.

There was impaired vision in one case.

The urine was free from albumen, casts, etc. no growth was obtained on culture.

Blood-examination showed slight polymorphonuclear increase and eosinophilia.

The average duration was about six weeks.

There were a few fatal cases—all among the females.

A change of station apparently gave benefit in all cases.

The minimum incubation period was 18 days.

Diets of the Bengalees.—Rice; fish and vegetables cooked in mustard oil; fresh fruits, etc.

The Gujrati and Kashmiri neighbours who had entirely escaped also used rice twice daily, but never used mustard oil in cooking and they did not use fish.

Source of the Rice.—Khalifa-ki-mandi is the principal grain mart in Allahabad. Here rice, as also other cereals, are sold wholesale and retail. There are several other marts in other quarters of the town. It is from these that most of the affected people purchased their rice. The main mart is a very insanitary market-place, being very damp and waterlogged during the rains. The sheds are also leaky in these godowns. The place is quite dry during the winter months. Kamala Bhandar, another rice mart from which many of the affected people purchased their rice, however, is a dry and pucca godown. In Khalifa-ki-mandi rice is imported from Bengal, Burma, and the United Provinces. Information was received that previous to the outbreak rice was not imported into Allahabad from Calcutta in any large quantity in any of the *mandis* or grain-shops.

Source of the Mustard Oil.—Most of the people (Bengalees) used bazaar made mustard oil, several samples of which when examined were found to be impure—adulterated with the oil from other grains resembling mustard seeds. Only a few people used pure oil and they entirely escaped (see later).

Distribution of the Cases.—Cases occurred in every quarter of the town, wherever the Bengalees resided.

The people affected belonged mostly to middle-class families living in pucca, dry, well-ventilated houses; and certainly none were very poor.

The biggest number of cases was in Lukergunj, a rather healthy locality so far as other common epidemics are concerned. In Lukergunj amongst a mixed population cases occurred only among the Bengalees.

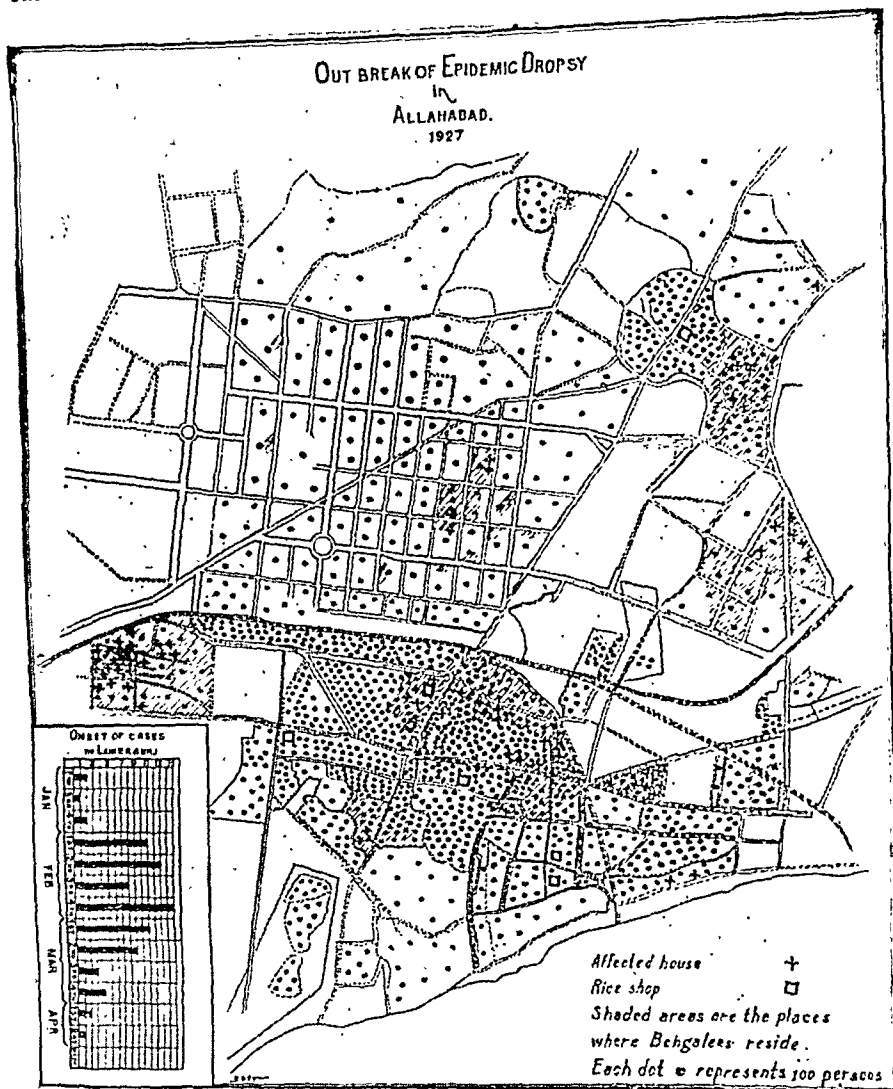

Infectivity of the Disease not Established.—The disease was not transmitted from person to person. During October and November, 1926, half a dozen imported families suffering from epidemic dropsy came from Calcutta for a change and were housed in different places in Allahabad. The people with whom they housed, as also their neighbours, entirely escaped, with the exception of one family. The incidence among the Bengalee families which received these

Of course, where both rice and oil have been stopped there has been improvement and no further new cases.

Can Rice be the Cause? Several members in a family were affected one after another, even when rice had been prohibited.

Cases occurred in three families who had stopped rice for nearly a month previous to their getting the disease.

A rice merchant of Calcutta with his family

patients from Calcutta suffering from the disease was thus less than among the rest of the Bengalee families.

Possible Causes.—Very likely bazaar made mustard oil (adulterated) is responsible, but may not be the only cause.

In one family fish and mustard oil were stopped as soon as a case broke out and there has not been another case during the epidemic.

The inmates of the jail prepare pure mustard oil for their own use and escaped.

Several families used pure mustard oil imported from some out-station and remained free from the disease.

In five families stoppage of mustard oil, while rice was being used all the time, led to recovery.

affected with epidemic dropsy came to Allahabad for a change. He brought some rice with him. He was strongly advised to discontinue the rice; the family then used locally purchased rice and were cured in six weeks.

Eleven families purchased more than a month's supply of rice from Kamala Bhandar about two months previous to the epidemic at about the same time and from the same set of bags. Of these seven were Bengalee Hindus, out of whom five families got the disease. The other four families were U. P. Muhammadans who entirely escaped.

CONCLUSION.

With our present knowledge it is difficult to say what are the exact causative factor or factors

of epidemic dropsy and whether it is a separate disease altogether from beriberi. As to what extent the nature of diet (food metabolism including excess of carbohydrate intake for generations), endocrines, and climate play their part is a problem that must await further solution. But one thing is certain and that is that epidemic dropsy or beriberi is not avitaminosis; much less does it correspond with anything resembling experimental avian polyneuritis. At present in food metabolism I would concentrate on carbohydrate metabolism in particular, for I have a suspicion that those races who are accustomed to take excess of carbohydrates for generations like the Bengalees are more susceptible to the disease. The Muhammadans here take very little carbohydrates and not a single up-country Muhammadan got the disease. The fact that the Bengalees were almost exclusively affected in the epidemic here is a very significant one, especially when all classes and races of people were living side by side under the same conditions. I cannot entertain the infection theory (from man to man) in this epidemic here for obvious reasons. It looks like a "rice-intoxication," but the epidemic may be a "toxi-infection."

I wish to record my thanks to Dr. R. N. Darbari, M.B., B.S., for going over the Lukergunj chart, and to Dr. M. N. Mitra, L.M.S., D.T.M., D.P.H., the Medical Officer of Health, for tracing out cases of epidemic dropsy in many of the consumers of common rice from certain rice-stores.

SODII SALICYLAS AND RHEUMATIC AFFECTIONS.*

By P. V. KARAMCHANDANI,
CAPTAIN, I.M.S.,

Officer Commanding, Indian Military Hospital, Pishin.

THAT sodium salicylate has stood the test of time and experience in acute rheumatic conditions is universally admitted. But its success in other, i.e., chronic rheumatic affections, has so far not been satisfactorily established. I have lately been making a special study of this kind of cases, and I am of opinion that sodium salicylate is equally efficacious provided it is administered by injection.

It may be noted that in acute rheumatic conditions, a toxin or toxins circulate in the blood and are therefore easily accessible to oral treatment. But in chronic cases the microbes are probably protected either by inflammatory overgrowth of connective tissue or by an excessive amount of carbon dioxide at the site of the lesion. In either

case, the drug administered by the mouth cannot reach the seat of affection in the full dose administered or without undergoing a change, so that the results obtained by this means have been varying and not sufficiently satisfactory to inspire confidence in the efficacy of the drug for such cases. To obviate these difficulties in the cases referred to above, the drug was administered by means of injection, and the results were found to be highly gratifying.

The action of sodium salicylate at the seat of affection may be represented by the following formula:—

Sodium Salicylate Salicylic acid.

Sodium salicylate coming in contact with nascent CO_2 (of which there is excessive production at the seat of lesion, for many of the patients treated described their affected parts as full of wind and almost bursting, and I have no doubt that the so-called wind is nothing more than the excessive CO_2 or combination of it) forms into salicylic acid, which exhibits its specific action.

I append a table giving a summary of the cases mentioned above of rheumatic affections other than acute treated by me with injections of sodium salicylate and give below short notes on some of them that appear to me of special interest.

Case 1. The patient suffered from a virulent infection. He had fever $102-104^\circ\text{F}$. and all except the shoulder joints were swollen. He was admitted into hospital for two months early in 1924, and was then treated with colloidal sulphur and iodine injections, sodium salicylate gr. xx t.i.d. combined with Atophan. His temperature did not come to normal until he was sent to a hot climate. The disease flared up again in the winter of 1926, when he was treated by me with sodium salicylate injections. He was relieved by the very first injection but four more were given.

Case 2. This was an obstinate and most stubborn case, resisting all forms of medical and electrical treatment. The patient always had dull pain with exacerbations of acute suffering in winter.

Case 9. In this case there was no fever, but the patient had excruciating pain which crippled him.

Case 16. This case presented a picture of glaucoma at first sight. As a matter of fact the case was so diagnosed by an eye specialist who advised the lady an operation. She was getting attacks of acute pain every night, starting in the eye and radiating to the cranium. They used to last three hours. She improved with the first injection and did not get any attack for seven days; on the eighth day she felt a dull pain in her left eye, but that too disappeared in fifteen minutes. She came for the second injection on the tenth day instead of the fourth day as advised, and had four more injections, but did not come for the sixth, although advised. When she left she had no pain.

Case 17. This case is of interest because sodium salicylate by the mouth always gave the patient

* Published by kind permission of the Director of Medical Services, India. The word "rheumatic" is used throughout this article to signify the conditions in which the essential pathological changes are confined to the fibrous tissue, and for want of an authentic name are variously described as rheumatics, chronic rheumatism, muscular rheumatism, tendinous rheumatism, rheumatic myositis, myalgia, etc., but have a definite existence.

NOTE.—Mild: Cases handicapped but not incapacitated.

Severe: Cases incapacitated but not confined to bed.

Very severe: Cases confined to bed during the attack.

immediate relief, but only so long as the drug was taken.

In all cases relief was almost instantaneous; patients who could hardly move through excruciating pain in the back and legs walked out within five minutes of the injection without any support and with no pain. Nor has any of them except Case 17 had a relapse up to the present day.

The technique adopted was as follows:—

For intravenous use, gr. 5 of chemically pure sodii salicylas was dissolved in 5.5 c.c. of normal saline, reduced to 5 c.c. by boiling, and given slowly into the vein. For intramuscular use 2 c.c. of normal saline containing 5 grains of sodii salicylas was injected into upper outer quadrant of the gluteal muscles. Intravenous injections caused no untoward effect at all, either immediate or late, but the intramuscular injections did and it was a severe local pain subsiding gradually in ten minutes. I think it is advisable to fore-warn the patients about this. A course of six injections, preferably intravenously, (two in a week) is recommended. This may, if necessary, be supplemented by sodium salicylate orally.

As a result of my observations on the cases referred to above, I have arrived at the following conclusions:—

(i) Rheumatic affections other than acute yield with equally satisfactory results to sodii salicylas if administered by injections, as by this method it exhibits double action, viz., (a) neutralizing CO_2 , thereby relieving pain immediately, and (b) through the salicylic acid formed thereby, displaying an antiseptic effect on the microbes; and

(ii) The nature of the infection in acute and chronic conditions of rheumatism is probably the same.

A NOTE ON THE INTRAVENOUS USE OF UROTROPINE IN INFLUENZA AND NEPHRITIS.

By AMULYA KUMAR BHATTACHARYYA, I.M.F.,
Medical Officer, Dalgram Dispensary, Tushbhandur,
Rangpur.

UROTROPINE, or hexa-methylene-tetramine, is a white crystalline powder and a condensation product obtained by the action of ammonia gas on formic aldehyde. It possesses an alkaline reaction in solution. For many years it has been used in medical practice, chiefly as a urinary antiseptic, though its value in this latter connection is very much open to doubt. In contact with the blood stream, it is supposed that the drug liberates formalin, and that its antiseptic action is due to this. The drug has also been tried in several other conditions, such as lithiasis, rheumatism, gout, cholecystitis, appendicitis, cerebro-spinal fever, encephalitis, meningitis, cystitis, etc.

In the influenza pandemic of 1918 I commenced to use urotropine intravenously in the hope that it would exercise some antiseptic influence on the septicæmic condition which is the cause of so much mortality in epidemic influenza. The results were so good that I have since adopted its intravenous use for treatment of all cases of influenza seen. As a rule, a single injection is sufficient to bring about a marked improvement in the patient's condition, and two or three injections bring about recovery. Even in cases where broncho-pneumonic

patches are present, results are good. In fulminant cases of influenza, this or any other remedy is of little avail.

The dosage given has been 15 grains dissolved in 4 c.c. of cold, sterile—preferably twice boiled—distilled water, given intravenously. The solution must not be boiled, as this causes decomposition of the drug. Ordinarily the sterile distilled water should be boiled again in a test tube; the required dose added under aseptic precautions, and dissolved in the cold water. The solution should be freshly prepared for each injection.

The injection should be given intravenously, and by this channel I have seen no complications. It is unsuitable for intramuscular or subcutaneous injection, as these are apt to be followed by local necrosis. In a few cases a marked reaction with fever and rigor is observed, but these subside almost at once.

The following six cases, out of a total of some fifty patients treated, will illustrate the method of use.

Case 1.—Hindu female, aged 25 years. History of influenza of some seven days standing, with fever of continued type, and much prostrated. Broncho-pneumonic patches in the lungs. An injection was given of 15 grains in 4 c.c., and was followed by a rigor with fever and profuse perspiration. The temperature dropped to subnormal that evening. A second similar injection was given the next day, and there was no reaction to this. There was no further fever and the patient made a rapid recovery.

Case 2.—Mahomedan male, aged 22 years. Seen on the second day of influenza. A single injection of 15 grains in solution was given and he made a rapid recovery. There was no reaction following the injection.

Case 3.—Hindu male, aged 35 years. Had been treated in hospital for influenza for some days, but the lung symptoms persisted, and the temperature remained elevated. Was given two such intravenous injections of urotropine, after which the temperature fell to subnormal, without reaction, and the patient made a rapid recovery.

Case 4.—Elderly Hindu male, about 50 years of age. Seen on the eighth day of illness when he was suffering from frank broncho-pneumonia, with extreme prostration. After a single injection, which was followed by no reaction, the temperature dropped to normal and the condition cleared up.

Case 5.—Mahomedan male, aged 25 years. Seen on the third day of illness. An injection of 15 grains was followed by a reaction with rigor and shivering. His condition immediately improved.

Case 6.—Hindu male, aged about 35 years. Influenza, complicated by lobar pneumonia, of 9 days standing. He received four injections of urotropine, after which the temperature fell to normal, and he made a sound recovery.

NEPHRITIS.

Encouraged by the result of using urotropine intravenously in cases of influenza, I commenced to use this drug intravenously in cases of both acute and chronic nephritis. Its effect in promoting diuresis and in eliminating dropsy appeared to be most encouraging. The quantity of urine passed increased, and in early cases albumin disappeared from the urine. In chronic cases improvement was definite, but no condition of cure resulted. The following are case records of such cases.

Case 1.—Elderly Hindu male, aged about 50 years. Duration of illness about 18 months, with much albumin in the urine, and marked œdema of the whole body. Was given three injections, each of 15 grains of urotropine intravenously on three consecutive days, followed by four twice-weekly injections. The œdema cleared up completely, and the patient appeared to be making most favourable progress. At this stage I was transferred to another station, but heard later that the œdema had recurred to a slight extent, but that the patient was much more comfortable than before.

Case 2.—Mahomedan girl, aged about 17 years, suffering from severe nephritis during pregnancy. After delivery the œdema persisted, with marked dyspnoea, and very scanty urine loaded with albumin. Severe constipation was also present. She received three twice-weekly injections, each of 15 grains; there was no reaction, the condition cleared up completely, and a permanent cure appeared to result.

Case 3.—Mahomedan male, aged 20 years, with nephritis of about 6 months duration. Marked œdema present all over the body; severe dyspnoea present, and the stools contained much mucus. A mitral bruit was audible, and the patient could not walk even a few yards. The urine was scanty and contained much albumin. In brief, prognosis appeared to be very bad. This patient received in all eight injections, each of 15 grains of urotropine, and appeared to completely regain his normal health. There was no reaction following the injections, and he has since been under observation for two years, and is now apparently in good health.

Case 4.—Hindu female, aged about 40 years. This was a case in a "rotten" state of health, with dropsy, dyspnoea, and profound anemia. The urine contained a large quantity of albumin. Eight injections, each of 15 grains of urotropine, were given, without reaction, and she appeared to make a sound recovery.

In connection with the above cases, it should be mentioned that full treatment with digitalis, purgatives, iron, and salines was administered simultaneously. Also a salt-free diet was prescribed.

It has been pointed out by some writers that urotropine irritates the renal epithelium and may cause hæmaturia after prolonged oral administration; but in the intravenous use of the drug I have never seen such symptoms to follow. In addition to influenza and nephritis, I tried the injections in a few cases of diabetes mellitus, since the drug is said to have an effect on the glycogenic action of the liver, but the results were not satisfactory.

CHLOROFORM ADMINISTRATION AND ITS DANGERS: AND THE ROLE OF THE EPIGLOTTIS IN ANAESTHETIC COLLAPSE.*

By LIEUT.-COL. F. J. PALMER, F.R.C.S.I.,
R.A.M.C. (Retd.),

Binnakandy, P. O. Silchar, Assam.

(A paper read at a meeting of the Surma Valley Division of the Assam Branch of the British Medical Association on 1st December, 1923.)

THE first portion of the title of this paper will be familiar enough to any of you who may have followed with interest the recent discussion

* We have received this paper, which was read as long ago as 1923, with special reference to the note on p. 587 of our issue for last October with regard to the safety of chloroform administration.—EDITOR, *Indian Medical Gazette*.

in the *British Medical Journal* on the subject of æther and chloroform. The second portion you will find to be a novelty.

When I promised your Secretary many months ago to read a paper on this subject, I was not aware that a controversy on the relative merits and demerits of æther and chloroform was about to take place. The publicity given to the question by this controversy and the publication by a writer in the *British Medical Journal* of 25th August, 1923, of a case in which a patient who had collapsed under chloroform had been restored by hooking up the epiglottis, decided me to make known the fact which I had first discovered some fifteen years before.

It may seem strange to you that one should have allowed so long an interval to elapse without making public a rather useful discovery, but one swallow does not make a summer, and cases of severe collapse under chloroform luckily do not occur every day, so it required many years before I could feel absolutely convinced that the great cause of death during chloroform administration was due to impaction of the epiglottis in the upper aperture of the larynx. Again, too, the fact that it was so difficult to convince even spectators who had witnessed a patient restored by hooking up the epiglottis, showed me that it would not be easy to gain belief.

In addition the *cacæthes scribendi* has not been one of my afflictions.

It is now some fifteen years ago since alarming collapse occurred in a patient on whom I was operating, and finding that breathing was not resumed, and that the ordinary methods of restoration in the hands of the anæsthetist including rhythmical tongue traction had failed, I took a hand, and hooking my finger far back at the base of the tongue felt the epiglottis apparently blocking the airway. On pulling the back of the tongue upwards and forwards, bringing with it the epiglottis, respiration commenced immediately. It was well nigh impossible to resist the suggestion of cause and effect.

A consideration of the minor difficulties of chloroform and æther administration had made me a firm believer in the finding of the Hyderabad Commission, and my object was to clear the airway. I had previously speculated on the possibility of Laborde's method of rhythmical tongue traction being efficacious because it pulled up the epiglottis.

In this case some degree of cyanosis preceded the collapse. The next case was of the type which would be described as immediate heart failure. I was about to commence a modified Whitehead's operation for piles, and was on the point of making the preliminary incisions, sitting in front of the perinæum, when the whole peri-anal region literally flashed white before my eyes, followed by a startled exclamation from the anæsthetist. I found the patient with widely dilated pupils and apparently dead. The mouth was forced widely open with a gag, the tongue pulled forward with a forceps, and on hooking

my finger and pulling the back of the tongue well forward no improvement occurred. Forcing my finger still further downwards I found the epiglottis impacted within the superior aperture of the larynx, and with difficulty managed to get my nail under its posterior edge and lift it up. After a slight pause respiration commenced. When the breathing became tranquil the anæsthetic was resumed, and the operation completed without any further difficulty.

This case naturally increased my belief in the efficacy of this method of restoration.

In another case in which similar collapse occurred I found the epiglottis impacted in the same manner, and on lifting it upward and forward (in relation to the patient) respiration again became normal. After a short time I removed my finger and respiration again stopped. A second lifting of the epiglottis restored it, and keeping it lifted for a little time the breathing became normal, and the operation was resumed.

And at long intervals other cases occurred and linger in the memory, some dozen in all. In one case in 1913, an old family friend, the collapse was immediate and resembled cardiac syncope. She, too, when apparently dead, was restored by hooking up the epiglottis as already described. In this case the sudden onset of pallor without preliminary cyanosis, and immediate cessation of the heart and respiration, with widely dilated pupil, suggested actual death. In such cases it may be necessary to carry out artificial respiration, with the epiglottis held up, to restore the patient.

Some cases occurred during the Great War, but of these I can only remember that they occurred and were restored by what I had now come to look upon as the routine method.

Two cases occurred in the winter of 1920-21. In one of these cases the appearance of death was absolute, with death-like pallor and widely dilated pupil. The heart, as tested by a stethoscope, had stopped for well over a minute. In this case, too, hooking up the epiglottis, which was impacted in the upper aperture of the larynx, followed by artificial respiration with the epiglottis held up, restored the patient.

This man at a subsequent operation also developed alarming symptoms, and was restored in a similar manner.

About the same time an infant developed grave collapse under chloroform, and appeared to be dead, but was restored in a similar manner.

In another case, a long way back in the sequence, the familiar collapse occurred, and, on attempting to hook up the epiglottis, I found it impacted as already described. I was, however, unable to get my finger under the posterior edge to lift it up, and the patient appeared to be dead. The airway had to be restored, and, with an effort, I was just able to press the epiglottis to one side, making no further attempt to lift it. This allowed air to enter and breathing recommenced. After a short interval I was able to

hook up the epiglottis, and the case gave no further trouble during the subsequent anæsthesia.

The most recent case occurred in Cachar when performing a thigh amputation for tiger maul. This patient, too, ceased to breathe and appeared to be dead, but was restored by hooking up the epiglottis.

Of other cases I have not so clear a memory, and any reference to them lies in old case books not at present in my possession, but there were some dozen in all of the severe type.

This may seem to you a large number, but it is spread over some fifteen years, and includes the surgical work of the war period which was very heavy. In some cases, too, the anæsthetists were young and lacking in much experience of chloroform administration. There is no doubt that in the hands of a skilled administrator the number of dangerous cases is considerably lessened, but they still occur.

It is entirely owing to having used this method of restoration for many years, that I attribute the fact that I have never known death occur under chloroform in any case on which I have operated, during a fairly large surgical experience.

Let us now consider the probable mechanism of this undoubted incarceration of the epiglottis in the upper aperture of the larynx.

I say undoubted, because I have felt it, but I have found it hard to convince others, and will doubtless find it difficult to convince you that such is the case. The ingrained reverence for authority is strong in most of us, and the teaching of to-day in the schools is that the heart fails first and not the respiration. The Hyderabad Commission, with a large experience of chloroform, held the reverse.

The first factor that emerges is that collapse under chloroform nearly always occurs in the initial stages of administration. At this stage the patient's reflexes, speaking generally, are much diminished but still present, and swallowing movements may occur, and always do if vomiting is threatened. At the same time the larynx is still capable of responding to the irritation of a heavy concentration of chloroform vapour by a certain amount of spasm. Given these factors a forcible attempt at inspiration, when the larynx is brought nearer to the epiglottis, may result in the latter being sucked down into the upper aperture of the larynx and there acting as a hinged valve.

This approximation of epiglottis and larynx may take place when, during muscular relaxation, the back of the tongue sags downwards or when a swallowing movement lifts up the epiglottis, approximating it a little closer to the back of the tongue.

Any further attempt at inspiration only leads to the epiglottis being more firmly imprisoned. The intrusion of the epiglottis into the sensitive upper aperture of the larynx leads to spasm.

When this spasm relaxes it is probably only

in the muscular relaxation which accompanies practical death.

In the case of a robust heart the interval between failure of the respiration and the subsequent failure of the heart may be long enough to allow of some warning cyanosis to be visible. In the case of a weak heart the interval between the two may be so short that pallor, with little or no preliminary cyanosis, occurs and the case appears to be one of primary heart failure. The action of the chloroform already circulating in the blood, doubtless, too, acts in a toxic manner on the cardiac muscle, but, in the great majority of cases, would not by itself alone be capable of causing a fatal result.

From the anatomical features of the epiglottis and its physiological rôle of preventing food or drink from entering the larynx, the passive sagging back of the posterior portion of the tongue during anæsthesia should have a similar effect to the active action of the back of the tongue in swallowing. Both would render it easier for the epiglottis to occlude the larynx.

It may be objected that, the epiglottis being attached to the tongue, traction on the tongue with forceps should lift out the epiglottis and restore the respiration. The practical fact remains that it does not always do so, and that I have felt the epiglottis incarcerated whilst considerable traction was being exercised on the forepart of the tongue.

In this connection I have found it possible to swallow water with my tongue held well forward by a handkerchief, without any going the wrong way. The traction was not, of course, as strong as in a case under anæsthesia, but the little experiment is suggestive.

It is possible that anatomical peculiarities, elongated glosso-epiglottidean folds, and a lymphoid tendency, may render the epiglottis more liable to become incarcerated.

Should these considerations be correct, as I believe them to be, they furnish an explanation of many procedures which experience has shown to be good practice during the induction of chloroform anæsthesia.

A gradually and regularly increasing strength of chloroform vapour is less likely to lead to coughing, and laryngeal spasm, and, at the same time, prevents the occurrence of retching, and reactionary vomiting.

Reactionary vomiting should be prevented from occurring whenever possible. Its threatened onset is indicated by up and down movements of the larynx, and frequently by a submental pallor extending over the anterior triangles of the neck.

These symptoms should be met by an increase in the strength of inhaled vapour. It is the young and nervous anæsthetist who is most likely to become alarmed by these signs, and allow the patient to almost "come to," which is usually followed by vomiting. In this connection it is probable that pulling forward the tongue and lifting the angles of the jaws, all tend to lift

the epiglottis away from the danger zone, but if these were efficacious in all cases no catastrophes would occur.

It is also evident that preliminary forcible chest pressure before beginning artificial respiration must tend to force out the epiglottis and clear the airway in some cases. All these measures are of proved value.

Equable administration I look upon as the most important factor in lessening the liability to grave symptoms during induction.

Personally I am not in favour of too much dilution with air during chloroform induction. This view is, I know, liable to challenge but, in a hot country at least, I have never seen any ill effects follow from keeping the mask quite close to the face. Sufficient air enters by the side of the mask. During very hot weather I have often used a folded towel laid gently over the mask, but not closely approximated to it over the nose. This tends to limit the escape of chloroform vapour into the outer air and hastens the onset of surgical anaesthesia.

Frequently one meets with patients who, after a small quantity of chloroform has been inhaled, fall into a condition of torpor which is not surgical anaesthesia, and who cannot be induced to breathe deeply by smacking or pinching. In some such cases only the first touch of the knife will induce them to make the full inspirations which end quickly in anaesthesia.

In these cases, previously breathing with extreme shallowness, the concentration of chloroform vapour should be lessened the moment deep inspirations begin, or a dangerous degree of chloroform in the blood may occur.

The deep regular breathing, with just a suggestion of stertor in it, is the best guide to the condition of the patient. Once this has begun dangerous symptoms only occur with the greatest rarity.

The paramount condition of keeping the airway clear is obtained in the case of "mucousy" patients (rare in chloroform administration) by frequently swabbing out the back of the throat with swabs clipped by holders or forceps.

I am rather in favour of fairly quick induction of anaesthesia. I have never seen any ill results follow if carefully conducted.

As regards the other great danger, delayed chloroform poisoning, it seems to me a moot question whether fatty hepatic degeneration is more likely to be induced by a weak blood concentration for a long period, or a somewhat stronger one for a short period.

And now as to the measures to be adopted should a grave case of collapse occur in spite of every care.

- (1) The gag to be placed in left side of mouth, which is to be forced widely open. In many cases it and the tongue forceps will be already in position, and this is the safest of all, but undesirable on other grounds. If not already applied mouth wedge

and gag should be absolutely ready, and if the gag is of the screw kind the screw should be opened sufficiently to allow the inter-dental plates to be in apposition, as moments may be precious.

- (2) The tongue forceps in the anaesthetist's left hand pulls out the tongue as far as possible.
- (3) The anaesthetist stands facing the patient's head on the right side.
- (4) Place the index or first two fingers, palmar surface to convex surface of the back of the tongue, and pull it upwards and forwards. In minor cases this will release the epiglottis.

In more severe cases, should the above procedure fail, the tip of the nail of the index finger must be insinuated under the free edge of the epiglottis. I have found this a matter of some little difficulty in two or three cases. The finger should then be slid along the lower surface, and the epiglottis lifted up and pressed by the pulp of the index finger against the back of the tongue.

Breathing will generally start immediately, as the finger in this position is probably a powerful stimulant of the respiratory centre. If it does not do so artificial respiration should be begun at once with the epiglottis held up.

Long, slender, so-called "artistic" fingers are a great asset in this manoeuvre.

In one extremely difficult case, so depressed was the epiglottis and so difficult to reach, that I could not get a finger tip under its edge. In such a case it would be necessary to press the epiglottis to one side and further downwards to allow air to enter round the edge, as was successful in this case, already narrated.

It is likely that traction on a sharp hook applied in the middle line at the back of the tongue would effect the release of the epiglottis, but of this I have no experience, having always found the finger sufficient. In the case of a mouth difficult to open widely, or an anaesthetist with short "stubby" fingers this manoeuvre should be tried.

In the worst and most desperate cases it may be necessary to carry out artificial respiration, with the epiglottis hooked up, for a short time. Forcible chest compression, which empties the chest of a good deal of vapour, should be a preliminary to any attempt. It should be remembered that, even if the respiration has failed first, the heart is in a desperate state too, and ventilation of the lungs is a step in lessening the toxicity of the blood and enabling it to resume its function.

Should the above procedure be carried out, chloroform administration, I believe, will quickly lose its terror, a terror so great that in the United Kingdom it is practically banned as an anaesthetic, and a new generation is growing up that knows not chloroform, although no other

anæsthetic has yet been found that possesses its advantages for emergency use.

I shall be more than pleased if I have contributed anything to the knowledge of its safer use.

I do not hope to convince many of you (the effects of early teaching are very strong), but if I can only succeed in getting you to consider a little the point of view I have endeavoured to put forth, and then in the hour of your patient's desperate need try the measures which I have explained to you, I shall be more than content.

For I believe that in that way safety lies.

A PRELIMINARY NOTE ON THE USE OF EPHEDRINE IN LEPROSY.

• By E. MUIR, M.D., F.R.C.S. (Edin.),

Research Worker under the Indian Research Fund Association, School of Tropical Medicine and Hygiene, Calcutta,

and

S. P. CHATTERJI, L.M.S.,

Physician to the A. V. Leper Hospital, Gobra, Calcutta.

It was found while using adrenalin in the febrile and asthenic condition which is not uncommon among the leprosy patients at Gobra Leper Hospital, that in a large proportion of cases nerve pains were remarkably relieved. As a result all cases of nerve pain were treated with adrenalin, 3 to 5 minims of 1 in 1,000 adrenalin chloride solution (P. D. & Co.) in 30 minims of saline being injected intramuscularly. With a few exceptions in which there was no effect, this remedy was found to relieve the pains within a very short time.

The relief caused by adrenalin suggested that ephedrine, which has an action similar in many respects to that of adrenalin, might have the same effect. This was found to be the case, and indeed ephedrine was found to be more efficient and lasting in its action, having besides the additional advantage that it can be taken orally, whereas adrenalin in order to produce any result has to be injected.

The nerve pains in leprosy are due to the presence of the *Mycobacterium lepræ* in the nerve trunks, especially those of the limbs, the ulnars and peroneals being the most affected. *M. lepræ* causes by its invasion of the nerve trunks a granulomatous condition of the connective tissue (epineurium, endoneurium and perineurium) surrounding the axis-cylinders. Considerable cellular proliferation may take place gradually during the quiescent phase (Muir, 1928) of the disease, but when reaction takes place and lepra cells are broken up either naturally or as the result of treatment, there is sudden vascular engorgement of the granulation tissue and the pressure on the axis-cylinders is suddenly increased, the nerve often becoming very much swollen within a comparatively short time. Were it not for these nerve reactions leprosy would be a comparatively painless disease; and a drug which while relieving this condition acts

at the same time as a tonic and improves the general condition of the patient is a very great boon to sufferers from this painful condition. Ephedrine sulphate given in hard gelatine capsules in a single dose of 0.05 to 0.1 gramme is sufficient in most cases to cause relief in from 45 to 60 minutes. The action lasts for 12 to 24 hours or even longer.

In many patients nerve reactions are caused in the course of treatment with iodides, each dose of potassium iodide causing pain which lasts for 24 to 72 hours or even longer. If ephedrine is taken by the patient whenever he feels the beginning of the pain, he is able to continue treatment in comfort until the granulomatous condition is cleared up and the iodide fails to cause further reactions. Often a single dose is sufficient, freedom from pain remaining till the reaction has passed off.

The immediate action of ephedrine is probably due to its causing contraction of the arterioles of the nerve trunks and thereby relieving their vascular engorgement. It appears at the same time to raise the reaction level of the patient and make reactions less severe; it does not appear however to interfere with the beneficial effects of iodide in gradually clearing up the disease in the nerves and other parts of the body.

The action of ephedrine is in contrast to that of opium and its preparations which only relieve pains to a slight extent and that only for a short time, while they have a harmful effect on the general condition of the patient.

While the action of ephedrine is very marked in the majority of cases, there are some patients who are not relieved. The reason for this has still to be investigated, as has also the effect of this drug on the blood pressure of the patient. A feeling of vertigo is caused in some cases and it is well to begin with the smaller dose mentioned above in the first instance, so as to test the patient's tolerance, a second dose being given after 45 minutes if there is no marked vertigo and if the nerve pains are not relieved by the first dose. If pain returns on the following day a smaller dose may suffice to produce the required effect.

The following cases illustrate the effects of ephedrine in thirteen cases in which it has been tested, the most of whom were under treatment with potassium iodide:—

Case 1.—I. M. There was pain in the right ulnar nerve after treatment. On giving ephedrine sulphate 0.1 gramme pain disappeared entirely within one hour. The next day pain returned slightly, but after giving 0.05 gramme the pain was relieved and did not return.

Case 2.—A. S. Severe pains in forearms, knees and legs after potassium iodide grains 10. Ephedrine sulphate 0.1 gramme caused pain to disappear within an hour.

Case 3.—S. K. R. Severe headache for 4 days following potassium iodide grains 140, which had been given frequently before without causing any headache. Ephedrine sulphate 0.1 gramme relieved headache within an hour.

Case 4.—M. M. Severe pain in ulnar nerve after potassium iodide 45 grains. After 0.05 of ephedrine sulphate there was no cessation of pain, but it was

entirely relieved after a second similar dose. Pains returned again the next day but were relieved by 0.05 gramme dose. There was a return at night but the same dose removed the pain which did not return, and patient slept well.

Case 5.—K. After potassium iodide grains 90 there was pain in the knee joints and the anterior margin of the tibiae. There was no relief after 0.1 gramme or again after a second dose of 0.05 gramme.

Case 6.—G. After potassium iodide (35 grains) there was aching of the whole body. Ephedrine sulphate 0.05 gramme relieved the pain within one hour but patient stated that he felt as if he was under a narcotic.

Case 7.—O. Pain in left ulnar nerve and knee joint after potassium iodide grains 240 and an injection of 7 c.c. of hydnocarpus oil. Ephedrine sulphate relieved pain, and the patient felt giddy.

Case 8.—J. B. Pain in the left ulnar nerve after potassium iodide grains 120 and hydnocarpus oil 6 c.c. Ephedrine sulphate 0.1 gramme relieved pain within 45 minutes.

Case 9.—J. S. Pain in right ulnar nerve after potassium iodide grains 12, was relieved by ephedrine sulphate 0.05 gramme.

Case 10.—D. S. Pain in ulnar nerve. Ephedrine sulphate 0.05 gramme gave no relief; 0.1 gramme, given half an hour later, relieved the pain but the body felt hot and there was a feeling of nausea. The next day when pain returned it was relieved by 0.1 gramme without these symptoms.

Case 11.—M. There was pain in the legs after potassium iodide grains 60. Ephedrine sulphate 0.05 gramme gave relief lasting for one hour. Thereafter as the pain returned a second similar dose was given and pain was relieved for the whole night, but the patient had a feeling of heat throughout the body. On the 2nd and 3rd days when pain returned it was relieved by 0.1 gramme and 0.05 gramme, respectively.

Case 12.—T. K. S. During a severe reaction there was pain in the ulnar nerves. Ephedrine sulphate 0.05 gramme gave relief for one hour, but due to a feeling of giddiness a further dose was not given. On the next day 0.05 gramme gave no relief.

Case 13.—A. E. D. During general leprous reaction 0.05 gramme was followed by vomiting. A second similar dose caused relief for 15 minutes after which there was sweating and palpitation. Two days later 0.05 gramme was followed by palpitation but there was no relief.

INDIAN KALA-AZAR IN A NEWLY-BORN CHILD.

By L. EVERARD NAPIER, M.R.C.S., L.R.C.P.,

*In-Charge of the Kala-Azar Research Department,
Calcutta School of Tropical Medicine,*

and

C. R. DAS GUPTA, M.B.,

Assistant under the Indian Research Fund Association.

In connection with any kala-azar investigations one of the questions that is repeatedly arising is, What is the incubation period in kala-azar? No satisfactory answer to this question has been forthcoming. Manson (1919) reports one case in which the incubation period appears to have been 10 days or less, and another case is reported by Napier and Muir (1923) in which the incubation period was not more than 14 days. On the other hand Napier (1927) reports a case in which the first symptoms appeared 18 months after the patient had left an endemic area, and from time to time cases crop up in Northern Europe and America in persons who have not been in known endemic areas for many years.

Recently, Shortt (1927) reported a case in which the incubation period was either 2 to 4 weeks, or 9 to 10 months, most probably the latter period. It thus seems probable either that the incubation period is not by any means constant, or that in certain instances the first clinical manifestations are so slight that they are not recognised by the patients themselves.

Another point in connection with kala-azar in India that recently came under discussion is the comparatively rarity of the disease amongst infants. At the recent F. E. A. T. M. Congress Lt.-Colonel W. C. Ross, I.M.S., made the statement that the disease did not occur amongst breast-fed infants and was exceedingly rare in children under the age of 2 years. Whilst it is

perfectly obvious that the age grouping in India is nothing like that of the Mediterranean type of the disease where, to quote a recent series of cases, 97 per cent. of the patients are below the age of six and 14 per cent. less than one year old, yet it is wrong to suppose that the disease does not occur amongst very young children. The Indian mother does not readily bring a very young infant to a dispensary for treatment, and when she does the doctor is faced with a distinct problem; blood for the serum tests is not easily obtained as it is not easy to introduce a needle into a vein in so small a child, either for the purpose of making a diagnosis or for administering treatment. It is therefore probable that the disease is much more common amongst infants than the official returns show.

During the last few years we have diagnosed and treated quite a large number of patients below the age of one year at the Calcutta School

of Tropical Medicine, but the case quoted below was infected at an earlier age than any other case which we have seen. This patient showed the first symptoms of the disease before it was four months old; it is interesting to note that in Paradiso's (1926) Catania (Sicily) series of 1,346 cases only three cases are below this age.

The case which is reported below is, thus, of interest in both these connections.

A Hindu male infant, said to be 6 months old but subsequently shown to be in its 8th month of life, was brought into the field dispensary at Kaorapukur on November 15th. The history given was that the child had been born in April 1927, had remained comparatively well for three months, but from July had suffered from continuous fever. Its temperature at the time was about 100°F., the pulse was rapid, the spleen could be felt about three inches below the costal margin and the liver was palpable. The blood was taken and the aldehyde test was found to be definitely positive. A diagnosis of kala-azar was made and in the ordinary course of events the treatment would have been commenced, but as the case was one of special interest it was brought to the notice of the senior writer who performed a spleen puncture in order to confirm the diagnosis. Numerous *Leishmania* were found in the smear and treatment was commenced; the child made satisfactory progress.

The child's parents were poor but healthy ryots. They had one other child aged three years; this was also quite healthy. The child had lived throughout in the village of Cheari in the 24-Parganas District of Bengal, a kala-azar endemic area. It had been breast-fed since birth.

As the mother showed no sign of the disease at all it is extremely unlikely that the child was suffering from the disease at birth. The history of the case, the size of the spleen and the condition of the blood, as shown by the aldehyde test, are all in keeping and suggest that the infection had lasted at least four months when the child was first brought for treatment.

Three points that are brought out by this case are:

- (i) that the Indian type of the disease does occur in newly-born breast-fed infants,
- (ii) that the incubation period in this case was almost certainly less than three months, and
- (iii) that infection was transmitted during April, the latter half, May, June or July.

A Mirror of Hospital Practice.

SUPRA-PUBIC CYSTOTOMY IN A CASE OF ENLARGED PROSTATE.

By BASHIRUDDIN AHMED,

Sub-Assistant Surgeon, Sadar Hospital, Comilla.

AN aged Brahmin, about 75 years of age, was brought to this hospital on the night of the 15th October, 1927, for treatment for retention of urine, due to an enlarged prostate. Retention had been complete for 72 hours, and an attempt made at Brahmanbaria hospital to pass a catheter had been unsuccessful. There was no history of previous retention.

On the morning of the 16th the patient was anaesthetised with chloroform and the bladder relieved by catheter. As there was constipation a dose of magnesium sulphate and an enema were given. In the evening the bladder had to be relieved by catheter, again under chloroform anaesthesia.

On the morning of the 17th an attempt was made to pass a catheter without chloroform, but was not successful. As the patient was old and debilitated and would not stand a daily dose of chloroform, supra-pubic cystotomy was decided upon and carried out by Dr. Rai J. N. Mitra Bahadur, Civil Surgeon, Tippera. The middle lobe of the prostate was found to be much enlarged. The patient's condition at the time of operation did not justify prostatectomy, so a drainage tube was put in and the bladder drained.

From this date until the 27th the patient did well, without any serious symptoms. On the 28th he passed red coloured urine, so the bladder was washed out daily for three days with boracic lotion until the urine again became normal.

The drainage tube was removed on the 7th December, and an indiarubber catheter was inserted through the supra-pubic wound and tied into position with his waist band, and a clip put on the end of it. With this arrangement the patient could get about, and relieve his bladder at stated intervals by releasing the clip. The catheter was removed from the supra-pubic wound a week later, and a rubber catheter inserted by the urethra, and left there for two days.

This was finally removed, as the patient could now pass urine spontaneously without difficulty by the urethra. The supra-pubic wound healed well, and the patient was discharged cured from hospital on the 25th December, 1927.

The interesting feature of the case is that the senile prostate diminished in size after operation to an extent sufficient to permit the patient to pass urine voluntarily, without compelling him to lead a subsequent "catheter life," whilst at the same time the operation of prostatectomy—which would have been a risky one in so aged and debilitated a patient—was avoided.

My thanks are due to Rai J. N. Mitra Bahadur for his kind permission to publish the notes on this case.

A CASE OF FOREIGN BODY IN THE VAGINAL MUCOUS MEMBRANE.

By R. K. RAJAGOPALAN,

Sub-Assistant Surgeon, Shivalkoppe.

A FEMALE infant, 9 months old, was brought to this dispensary with a history that a paddy grain had become embedded in her vagina. It seems that the parents used to allow the child to play on the ground in the fields, and the baby gradually crawled on her chest to a heap of paddy grain close by. Owing to her lively kicking movements, a grain of paddy had accidentally entered the vagina and had become firmly embedded in the mucous membrane. The baby's mother was horrified and did her best to get it out, but without success. Other relatives also failed, and the child was brought to the dispensary three days later.

There was a slight collection of purulent matter in the posterior fornix. Being unable to get even my little finger into the vagina, an ear speculum was inserted, and the vaginal canal explored. The paddy grain was now seen, but an incision had to be made into the perineum to get at and remove it. The slight wound was then sutured. The parents never brought the child back to the dispensary for re-examination.

A CASE OF INCISED WOUND OF THE LUNG.

By A. S. DAWSON, L.M.P.

Thonze, Tharrwaddy District, Burma.

THE following case appears to me to have important medico-legal bearings, since, had one not known the exact history of what happened, the case might easily have been mistaken for one of attempted homicide.

Mg Po Myin, aged 25 years, a male Burman of Letpangone village, was brought to the Thonze hospital on the 22nd May, 1927, with the history of having sustained the following injury. He was descending a bamboo ladder attached to the house where he was living, when he suddenly slipped and fell a distance of some 12 or 13 feet. At the time when he was descending the ladder he had in his hand a long sharp knife, or dao, his hand resting on his left shoulder: as he fell this slipped off and struck him on the back over the apical region of the left lung and penetrated the pleura and the lung.

The knife was extracted by his relatives, the wound dressed with a filthy cloth, and the patient brought to hospital. On admission a wound was found, 3 inches in length, gaping, and with frothy blood escaping at each inspiration from it. A considerable quantity of blood had already been lost.

The wound was cleaned and sutured under an anæsthetic and dressings applied. Unfortunately

it then suppurated and traumatic pneumonia developed, followed by pyopneumothorax. The pus was eventually evacuated, and with good drainage the patient made an uneventful recovery. He has subsequently been seen and is in good health.

Had the patient died from the injury, it seems likely that questions as to possible homicide might have been raised, since it would be extremely difficult for a person to stab himself in the apical area of the left lung at the back with a long knife.

MYIASIS IN A LEPER.

By G. R. RAO,

Medical Officer, Leper Asylum, Cuttack

CASES of myiasis have been reported in medical journals from time to time, but the following case deserves notice on account of its peculiarity.

Joga Behara a B₃—A₂ case of leprosy in this asylum, suddenly developed an alarming oedema of the whole face on the morning of the 5th December, 1927. The oedema was specially marked around the orbits. The previous night he was all right except for a little bleeding from his nostrils. He had no other signs or symptoms worthy of note. His nose was examined, and as he had a foul discharge, a nasal douche with warm carbolic lotion 1 per cent, was ordered. Half an hour after the douche a dead dipterous larva came out of his nose on sneezing; and he brought it to me. As I was then busy with other work, I could not spend much time in identifying the larva. But from the observation made for a short time, I came to the conclusion that it was a dipterous-cyclorapha larva as it had an undifferentiated head. The patient was instructed to preserve the larva with any other that might come out of his nose. But unfortunately by some misunderstanding he threw the specimen away, along with several others that came out of his nose during the course of the day.

Larvæ of the following families are said to commonly infect the wounds and natural orifices of the human body in this country:—

(1) Cestidæ. (2) Sarcophagidæ. (3) Muscidæ.

In this asylum Sarcophagid flies and Lucilia flies—(blue and green bottle flies) are very commonly found. Possibly the larvæ might have been either Sarcophagid or Lucilia.

Stitt in his book on *Practical Bacteriology, Blood work and Parasitology* says that Lucilia flies are very fond of the foul odour of an ozonous discharge from the nose. Possibly in this case the foul discharge from the nose might have attracted a Lucilia.

The patient was treated with the same douche of warm carbolic lotion thrice a day and he made an uneventful recovery in four days. Repeated attempts to recover some living larvæ by gentle scraping failed.

Whenever cases of sudden swelling of the face with no fever or no albumin in the urine and no other symptoms of note occur, especially in lepers, the possibility of myiasis should be considered.

ON SOME CLINICAL FEATURES OF MALIGNANT TERTIAN MALARIA.

By KALI GATI BANERJEE, M.B.,

Noapara, Ganutia P. O., Birbhum.

DURING the months of September, October and November, 1927, malaria of malignant tertian type has claimed its victims by hundreds in this district of Birbhum, and I was called in to see many of these cases as a village practitioner,—some of them on their death beds, others less critically ill. Unfortunately facilities for microscope work are not available here, and my observations have had to be of the clinical type, aided by therapeutic results. Before giving details of certain cases, it may be as well to give a short summary of the types of cases observed and of the lines of treatment adopted.

Age.—Persons of all ages were subject to attack, but children of 2 to 6 years of age appeared to be the most susceptible, and to succumb most readily.

Types of Fever.—The types of fever seen may be classified as follows:—

- (1) Convulsive type.
- (2) Diarrhœic type.
- (3) Miscellaneous; viz. (a) hyperpyrexial type, (b) urticarial type, and (c) typhoid type.

Convulsive type.—These patients were mostly male children of from 2 to 6 years of age. The majority of them proved fatal despite the most vigorous measures. Most of these cases showed a remission on the second day, but had severe fever on the third day with convulsions, which sometimes persisted till the fourth day. The number and frequency of the convulsions seemed to bear no relationship to the prognosis. Another peculiar feature of these cases was that all of them had intractable tympanites.

Choleraic and Diarrhœic type.—The majority of these cases were adults, all seen being males. Bilious vomiting and diarrhœa, often with blood and mucus in the stools, were prominent features in almost all cases. In a few, however, vomiting was absent, but the intensely toxæmic state of the patient and the diarrhœa or dysenteric condition present might have led one to diagnose the case as one of severe bacillary dysentery. Diagnostic features of these cases however were that (1) the intestinal symptoms made their appearance concurrently with the paroxysm of fever. (2) the intestinal symptoms disappeared during the remissions of fever. (3)

Murphy's sign was present in all cases; and, finally, (4) a most important diagnostic point was that there was tenderness of the spleen in these cases. In addition (5) pain was present in the umbilical region, and (6) acetone and albumin were present in the urine.

Miscellaneous types. (a) *Hyperpyrexial type.*—These cases ran a short course of from three to five days and were less fatal than might have been expected.

(b) *Urticarial type.*—Only one such case was seen, but it tended to confirm Sinton's statement that the malarial paroxysm is of the nature of an anaphylactic reaction. The patient was a boy aged 12 years, who complained that he had fever every alternate day, accompanied by painful itching all over the body and the appearance of local swellings which came out within a few hours of remission of the fever. After an interval free from symptoms he had a similar attack in the last week of September; after this relief for some days, without treatment; then five relapses of fever, followed by a sixth, when he came to see me. I found the swellings to be of typical urticarial type. Quinine therapy completely cured the malaria, and also the condition of urticaria; since then the boy has been on systematic administration of quinine, and has remained free from all symptoms.

(c) *Typhoid type.*—These patients show a remittent type of temperature chart for from three to four weeks. The temperature is usually highest in the evenings, and with this rise of fever there is a tendency to diarrhœa. Typhoid-like stupor, however, is absent, but the presence of a slow pulse rate with intestinal symptoms may mislead one to diagnose the case as one of enteric fever. Quinine therapy, however, cured the condition and clinched the diagnosis.

Treatment.—The treatment adopted wherever possible was Sinton's method of the administration of alkalis, followed by quinine orally. Calcium salts were also administered in the more severe cases in the hope of controlling the convulsions and with a view to combating anaphylaxis. In the convulsive cases potassium bromide proved useless. In such cases resort was had to intramuscular injections of quinine, saline infusions, and adrenalin, but with little effect. In very severe cases drinks of glucose-brandysodium bicarbonate solution were given orally in the hopes of combating acidosis, together with the alkali and quinine treatment.

The following are notes on some of the more interesting cases seen.

Case 1.—Male, 1 year old. His elder brother, aged 10 died in the same house a week previously, on the 3rd day of fever with convulsions. When seen had had fever for 2 days with convulsions. Was treated by an alkaline mixture orally containing potassium citrate, sodium bicarbonate, and digitalis; followed by quinine in acid solution. Also adrenalin solution, 4 minims by the mouth 4-hourly and otherwise when necessary.

Made a complete recovery after having taken 36 grains of quinine orally in 36 hours.

Case 2.—Male, aged 5 years. Previous history of malaria off and on, with (?) epilepsy. Present attack commenced with chill and ague, a remission on the 2nd day, with convulsions and twitchings of the facial muscles on the 3rd day. Treatment similar to that in Case 1 was given, but the parents refused to allow quinine to be administered to the child whilst he was having high fever. Glycerine enemas were given, and magnesium sulphate added to the alkaline mixture, but the child died the next day in a state of convulsions.

Case 3.—Male, aged 6 years. Previous history of asthma and (?) epilepsy. Present attack set in with chill and rigor, and remission on the 2nd day. Convulsions set in at 9 a.m. on the 3rd day. When seen by me shortly afterwards, he was unconscious, with a temperature of 105° F., pulse rate 160, respirations 48, and stertorous. The spleen was not palpable, but tympanites was very marked. Turpentine stupes were given and $\frac{1}{2}$ c.c. of pituitrin intramuscularly, followed by 10 grains of quinine intramuscularly. Rectal saline and sodium bicarbonate were given per rectum; hydrotherapy resorted to; and an alkaline mixture with potassium bromide given when the patient was able to swallow. Death ensued however at 8 a.m. on the morning of the 4th day of illness.

Case 4.—Female, aged 6 years. Previous history of occasional fever. Present attack started with ague and chill, and remission on the 2nd day. Convulsions set in on the 3rd day. Quinine and alkalies were now prescribed, and after the administration of 24 grains of quinine in 12 hours the patient regained consciousness. The next morning, however, fever recurred with severe rigors, and she died.

Case 5.—Male, aged 37 years. Seen on the 3rd day of fever. A condition present of bilious vomiting and diarrhoea with blood and mucus in the stools. With the remission of the fever the intestinal symptoms abated. Murphy's sign was strongly positive; the liver enlarged and tender; the spleen enlarged, and jaundice present; temperature 102° F., pulse 120, respirations 32. This patient was given a strongly alkaline mixture, followed by quinine in acid solution. He took 160 grains of quinine in solution within 54 hours, and was completely cured.

Case 6.—Male child, aged 1 year. Remission of fever on the 2nd day, followed by convulsions on the 3rd day. The convulsions especially affected the left side of the body and appeared to begin from the lips, with groaning. Temperature 101° F., pulse 140, respirations 36. Given subcutaneous saline with adrenalin, 10 grains of quinine intramuscularly, and finally alkalies and quinine orally. The total dosage of quinine given was 8 grains orally within 6 hours, and the intramuscular dose of 10 grains, but the patient died on the 3rd day.

Case 7.—Female infant, aged 5 months. A similar history to that of Case 6, with convulsions on the 3rd day; temperature 105° F., pulse 168, respirations 38, and very marked tympanites. Hydrotherapy was given, 2 minims of adrenalin solution every 2 hours by the mouth, and an alkaline mixture containing sodium bromide, alternating with quinine and calcium lactate, taken in powder in honey. Drinks of glucose, brandy, and sodium bicarbonate in water were given by the mouth. This patient took 8 grains of quinine hydrobromide within 12 hours by the mouth and made a splendid recovery.

Case 8.—Male child, aged 4 years. Two convulsions with fever on the 2nd day of illness. On the 3rd day the temperature rose to 101° F., with unconsciousness, and convulsions, the pulse almost imperceptible at the wrist, very marked tympanites, and an enlarged and palpable spleen. He was at once put on to an alkaline mixture containing digitalis, followed by 5 grain doses of quinine in solution every 3 hours, the dosage of

quinine then being reduced to 3 grains for 3 doses, and then replaced by 3 grains of euquinine in powder with honey, calcium lactate being added to the powder. A drink containing brandy, glucose, and sodium bicarbonate was also given freely. The patient made a sound recovery after taking 50 grains of quinine within 42 hours.

Case 9.—Male child, aged 2 years. Had had fever for 4 days before being seen. No convulsions present, but when seen child was rolling his head from side to side, was unconscious, and the pulse could not be felt at the wrist; temperature 102° F. A subcutaneous injection of adrenalin was administered at once, but the child died before any further measures could be taken.

Case 10.—Male, aged 22 years. History of fever for 4 days, with remission on the 2nd day. On the 3rd day excessive vomiting set in with fever, and the passage of stools containing blood and mucus. The liver was enlarged and tender; Murphy's sign positive, the spleen enlarged and a certain amount of jaundice present; temperature, when seen on the evening of the 3rd day, normal, and pulse of low tension. Was given adrenalin in 10 minim doses orally, followed by an alkaline mixture and quinine in solution. In all he took 44 grains of quinine within 8 hours and made a complete recovery.

Case 11.—Male child, aged 12 years. Urticarial type of case as detailed above. Liver enlarged and tender; intense jaundice present, Murphy's sign strongly positive, anaemia marked, spleen very much enlarged. At first given an alkaline mixture to which sodium salicylate and urotropine were added, followed by 10 grains doses of quinine in solution, twice daily. Calcium lactate also given in powder form; and later the alkaline mixture, but with quinine pills administered. This patient took 40 grains of quinine in solution within 48 hours and escaped the expected next attack of ague and urticaria.

Case 12.—Female child, aged 5 years. Had a previous attack of malaria about 2 months before. Present attack began just before midnight with rigors, convulsions every 5 minutes, and unconsciousness. I saw her an hour before her death. The pulse was imperceptible, and the first cardiac sound scarcely audible. The respirations were 40 to the minute, stertorous, and with signs of œdema of the lungs; temperature 103° F. The knee jerk was markedly accentuated in the right leg, but normal in the left leg. Kernig's sign was absent, but there was definite rigidity of the neck muscles. The spleen was just palpable. A special feature of the case was the presence of marked internal strabismus. An immediate injection of $\frac{1}{2}$ c.c. of adrenalin solution was given, and 1 grain of quinine intramuscularly, but the patient died an hour after having first been seen.

Remarks.—My experiences in this outbreak of a very virulent type of subtertian malaria are probably akin to those of other medical men in India; yet certain points seem to impress themselves on me as the result. The main points which I should like to bring forward, are (1) that once the malignant tertian parasites have got hold of the cerebral circulation, so to speak, most usual measures are hopeless. I have not tried the effect of intravenous quinine in such cases, but the condition is one where all the usual emergency measures seem almost useless. (2) Quinine in big—even heroic—doses may safely be administered to these severe cases of malaria, even when their temperature is elevated. The medical practitioner who hesitates, is lost; push quinine in generous doses is the best working rule. (3) Sinton's method of treatment by

administration of an alkaline mixture, followed by quinine in solution, appears to me to be the most efficacious mode of administration of quinine. (4) There are certain adjuvants to this line of treatment which appear to be worthy of trial, in such severe and fulminating cases. The first of these is administration of calcium salts; the second, if acidosis is the condition underlying the critical state in malaria, the administration of glucose-brandy-sodium bicarbonate drink in large volumes by the mouth. According to the *Medical Annual*, 1927, article on diabetes, administration of 50 grammes of glucose by the mouth can cure the acidosis due to starvation within an hour.

I have not tried intravenous quinine for such cases. It is a line of treatment in village practice which makes one pause before venturing upon it. 'Better to bear those ills which we have than fly to others we know not of.' But of one fact I rest assured; that when the village medical practitioner is faced with epidemic and virulent subtertian malaria, such as was present in this district last autumn, quinine—in adequate doses—is his sheet anchor of treatment.

A NOTE ON THE TREATMENT OF CHOLERA.

By A. S. DAWSON, L.M.P.,

Medical Officer, Thonze, Tharrawaddy District.

THE treatment of cholera to-day is by no means standardised, and many modifications of Sir Leonard Rogers' hypertonic saline method have been introduced. After trying different methods I have now adopted a routine one which gives some 80 per cent. of cures. In a recent series of six cases, I only lost one—a boy of 8 years of age, not seen until 18 hours after the onset of the attack, and in a condition of severe collapse; in fact I doubt whether any line of treatment would have saved this patient.

My routine method is to first administer essential oils' mixture, whilst preparations are being made for the administration of saline subcutaneously. The sooner the case is seen, of course, the better the prognosis, for by more than six hours after the onset of the attack the patient may have been seriously depleted of fluid, and the renal and systemic circulations be endangered.

The following mixture is given in doses of one ounce every half hour till 8 to 10 doses have been given;

R Spirit. ætheris	m 30
Ol. caryophylli	m 5
Ol. cajuputi	m 5
Ol. juniperi	m 5
Acidi sulphurici dil.	m 15
Misce.			
Aquam ad.			oz. 1 per dose.

In the meantime one pint of hypertonic saline is slowly administered per rectum from an ordinary douche can, and 3 to 4 pints of hypertonic saline should be given into the cellular subcutaneous tissues. For the latter an ordinary douche can may be used, fitted with rubber tubing and a hollow needle. The temperature of the fluid should be at or below normal.

Body temperature, 99°F; the saline should be given at 100°F.

Body temperature below normal; the saline should be at 102°F.

Body temperature 101°F. or more; the saline should be at or below normal.

The temperature is easily tested by running the fluid over the bulb of a thermometer, and cold or hot sterile saline added to the fluid in the douche can till the required temperature is reached.

For children the doses, both of the oral mixture and of hypertonic saline, should be halved. If the saline per rectum is voided, it should be repeated until it is retained. It is especially in the case of children that the saline should be given into the cellular tissue, since it is difficult to introduce a fairly large bore needle into the vein in a child without transfixing the other side; further, many physicians are not expert in intravenous administration. At the same time cardiac stimulants are given as necessary; e.g. gr. 1/100th of digitalin or strophanthin hypodermically.

If suppression of the urine occurs apply dry cupping over the loins. If still no urine is passed, it is necessary to give alkalines intravenously, the following injection being given;

R Sodii chloridi	grs. 60
Sodii bicarbonatis	grs. 160
Aquam distill.	ad oz. 20

This to be followed up, if necessary, by hypertonic saline intravenously.

With regard to diet milk, soup, and alcohol should be eliminated, and barley water and thin arrowroot congee given. Old and debilitated patients may be given a 5 per cent. solution of glucose by the mouth.

A point to be remembered with regard to the essential oils' mixture is that it should always be given in the manner indicated above, and that its value is much less if the duration of the case is more than 6 to 8 hours. In such patients, when seen early, the essential oils' mixture alone may be sufficient, without any subcutaneous or rectal saline. The mixture has a distinctly stimulating, as well as bactericidal action.

Lastly, with regard to prophylaxis, for all contacts one dose of the essential oils' mixture should be given on one or two consecutive days, or until all risk of infection has ceased. The mixture may also be used for general administration to the households in the neighbourhood until the epidemic has died down.

Indian Medical Gazette.

APRIL.

THE BURMA GOVERNMENT RESOLUTION ON INDIGENOUS MEDICINE.

WE publish elsewhere (in our "Current Topics" section) in this issue of the *Indian Medical Gazette* the full text of this resolution. The most important terms of reference of the Committee appointed are (a) "to examine and report on Burmese systems of medicine; and (b) to consider whether Burmese systems of medicine (*sic.*) can be improved, and if so, in what way."

The resolution suggests that there is an intention to establish courses of training in the Burmese systems of medicine at Government expense. If this action is taken, there will soon be at least three Indian indigenous systems of medicine in which training will be given under the auspices of Local Governments. It is a pity that Madras and the United Provinces should have taken such precipitate measures for establishing schools of training in the indigenous systems. The first logical step in any such matter is to arrive at a clear understanding of the systems concerned, and the next to consider whether it is desirable or not to restore those systems at Government expense. State-aided education in technical subjects is expected to concern itself with methods which are generally recognised as being the most efficient, and it is regarded as wasteful to encourage inefficient and antiquated procedures. As there is an insistent demand for the restoration of the indigenous systems, it is necessary first to find out exactly what these systems consist of, and to let the people understand clearly what good or harm is likely to result from expenditure from the public purse in connection with their restoration.

It would be interesting and useful to establish an enquiry into the principles and practice of the various indigenous systems; money spent on such an investigation would not be wasted. There are many scientists in India who are in no way associated with medicine who would be competent to conduct an enquiry of this kind; their findings would command respect, they would be impartial, and would have a great educational value.

The attitude of the American Government towards the indigenous systems of medicine in the Philippine Islands is worthy of serious consideration in this connection. Every one is allowed to practise medicine according to any "system" which he may select, but a license is given only on condition that the candidate has taken out an approved course of training in the preliminary scientific subjects, *viz.* chemistry, biology, anatomy, physiology, etc. In other words, it is held

to be essential that the medical man should have a sound educational foundation on which to build his professional knowledge, whether he intends to practise scientific medicine or one of the indigenous systems.

In India there is a tendency to think that any one is fit to be entrusted with the care of the health of the community, provided that he has a smattering of knowledge of drugs. In the present evolution of medical relief in India there will for many years be scope for the village doctor who has had no scientific training, but governments ought to act with a full sense of responsibility when they lend themselves to the training of young men in methods which are regarded by the rest of the world as inefficient and obsolete. If the students had a sound preliminary training and a good knowledge of the basic sciences, they could be trusted to pick out what is good in the indigenous system; but to encourage them to plunge straightway into a study of the indigenous systems without a preliminary education in scientific methods is to perpetuate the very evils which the governments concerned are trying to eradicate.

It is to be hoped that the Burma Committee on the indigenous systems will do their work thoroughly and will give us a reasoned statement of the advantages which can be derived from State aid to the old systems; in any case they ought to insist on the possession by every candidate of a good preliminary education in biology, chemistry, anatomy, and physiology; otherwise they will commit themselves to the attitude that the whole of the rest of the world is wrong in regarding disease as something that must not be handled except by men who have been educated on the best possible lines.

A dangerous suggestion, indeed, lies in the very use of the word "system." Every other branch of human knowledge has got away from the idea that there are various "systems" which are worthy of encouragement. There is only one system of chemistry, one system of anatomy, one system of biology. Everywhere there is a serious attempt to arrive at the truth, and the same principle ought to apply in medicine. What would the world think if a movement were to arise in India for the restoration of astrology, or of alchemy? Is it conceivable that the great army of medical scientists in every country of the world are working on wrong lines, and that therefore we must discard the vast body of knowledge which they have built up? There can be only one "system" of medicine, not the homeopathic, nor the allopathic, nor that indigenous to any country, but scientific medicine, and all our efforts ought to be directed towards the building up of a medical science which must necessarily be world-wide and international, it will necessarily be the most efficient for coping with disease. A common fallacy exists that the ancient systems are cheap: inefficient methods are never cheap and if any standard of attainment is selected, the scientific method of attaining to

that standard must be the cheapest. Let us concentrate first of all on something that can be accepted by everyone and institute an independent enquiry into the nature and methods of the systems for which special claims are made.

THE SEVENTH CONGRESS OF THE FAR EASTERN ASSOCIATION OF TROPICAL MEDICINE.

THOSE who were present at the recent Congress of the "F.E.A.T.M." will agree that the *Indian Medical Gazette* was not guilty of exaggeration during the pre-Congress period when it laid stress upon the importance of the forthcoming meeting to be held in Calcutta.

By universal consent the Congress is now regarded as the most valuable symposium on tropical medicine which has ever been held.

Those who worked so hard in preparing for the Congress are to be heartily congratulated on the brilliant success which resulted from their efforts. The Government of India are to be congratulated on their generous support; a whole army of enthusiastic collaborators are to be congratulated; but everyone will agree that the chief share of the credit is to be attributed to Lieut.-Col. J. Cunningham, I.M.S., the General Organising Secretary, and to Lieut.-Col. A. D. Stewart, I.M.S., the Local Secretary for Calcutta. The Congress was fortunate in securing organisers whose ability and energy enabled them to overcome the thousand and one difficulties which were encountered.

It was feared that the Seventh Congress would compare rather unfavourably with the Sixth on the social side, but, thanks to the generous help of His Excellency the Governor and Lady Jackson and a host of other helpers, Calcutta well maintained its reputation for hospitality. From the scientific point of view also a very high standard had been set by Japan, but here also India rose to the occasion in a most spirited manner, and the only complaints which reached our ears were that the time was far too short for the splendid programme of papers and debates.

Calcutta is the gateway of India from the Far East; it is also the centre of India from the point of view of accessibility and capacity to absorb a large army of guests. The Congress found an ideal meeting place in the old Medical College of Bengal and the new Calcutta School of Tropical Medicine. Calcutta is the commercial, scientific, and medical capital of India, and so it was eminently suitable to be the meeting place for the Congress. Never in her history has India seen such a gathering of medical experts. We might have expected difficulties in connection with language, but almost all of our visitors spoke English with great facility, and so the Congress was practically unilingual. The obstinate refusal of the Anglo-Saxon peoples to cultivate foreign languages may ultimately turn out to be a blessing in disguise, as English is rapidly becoming the *lingua franca* of the Far East.

In Japan one of the sessions was held in Esperanto, but it was noteworthy that the members who attended failed to understand the chairman when he announced in Esperanto that the proceedings had terminated. However unfair it may be that English is singled out for preferential treatment, there is no doubt that the most practical solution of the language difficulty is for each country in the East to adopt English as its second language.

J. W. D. M.

A CHANGE OF EDITORSHIP.

WHILST we cannot refrain from congratulating Lieut.-Col. J. W. D. Megaw, V.H.S., C.I.E., I.M.S., on his recent promotion last February from the post of Director of the Calcutta School of Tropical Medicine to that of Inspector-General of Civil Hospitals, Punjab, yet we most sincerely deplore his loss to the Calcutta School of Tropical Medicine, and his relinquishing the post of editor of this journal. The *Indian Medical Gazette* has had many distinguished editors, but never one who was more suited to the editorship of this journal than Colonel Megaw, who has been its editor since 1921. The *Gazette* is a journal which is primarily intended for the general practitioner, whether in town or *mofussil*, and it was in catering for this public that Colonel Megaw showed his great breadth of outlook and his knowledge of the requirements of this class of reader. At the same time he always appreciated fully the importance of scientific papers, especially those with a direct clinical application. Whereas the progress made by this journal in India is undoubtedly due to the particular appeal which it has always made to the general practitioner—largely through its "Current Topics," "Mirror of Hospital Practice" and "Reviews" sections, for which Colonel Megaw was largely responsible—its more scientific sections are perhaps chiefly responsible for its more international reputation.

It has been in keeping the balance between these two aspects of this journal, and thereby satisfying both classes of readers, that Colonel Megaw has been so successful. The circulation of the *Gazette* is not the direct concern of its editorial staff, but we are informed that this has more than doubled since Colonel Megaw took over the editorship seven years ago.

Colonel Megaw has gone, but the good work which he has done still remains. We hope, by following the traditions which he has laid down, that the *Gazette* will not only hold the position in which he has left it, but that its rate of progress will be maintained in subsequent years.

We must congratulate Colonel Megaw on his promotion. We have lost him as our editor, but we sincerely hope that we will still retain his services as one of the most important contributors to this journal.

THE INDIAN MEDICAL YEAR, 1927.

WE regret very much that this year it has been necessary for us to depart from our usual practice of publishing our annual supplement, the *Indian Medical Year*, with the April number of the *Gazette*. This review is now ready, but various circumstances have made it necessary to postpone its publication until next month, May. Our annual index is to be published with the current (April) number; this will bring the number up to full weight for postage. No less than fifteen contributors have sent in summaries for inclusion in the annual review and we hope that it will be truly comprehensive.

SPECIAL ARTICLE.

OBSTETRICS AND GYNÆCOLOGY IN THE DAYS OF THE PATRIARCHS.

By V. B. GREEN-ARMYTAGE, M.D., F.R.C.P. (Lond.),
LIEUTENANT-COLONEL, I.M.S.,

(An address delivered to the Medical Section of the Asiatic Society of Bengal on the 14th June, 1926.)

Note.—This address was originally published in *The Journal of Obstetrics and Gynæcology of the British Empire*, Vol. XXXIV, No. 3, but we have received so many requests from our readers in India that it should be re-published in this country, that we publish it with the kind permission of Mr. Comyns Berkeley, Editor of that journal.—EDITOR, *Indian Medical Gazette*.

My particular reason for thinking that the subject on which I am about to address you might be of interest to you arose recently when I was delving in the Bible for anthropological evidence of endocrine influence, such as might bear upon the matter of the "hirsute man of action" and "the smooth man of thought," and whereas I might have mentioned Nimrod, Goliath, Samson, Judith, or Jezebel, each of them respectively illustrative of hyper-adrenalism, hyper-pituitarism, and hyper-thyroidism, I chose rather to quote the birth of Esau and Jacob which, from an Anglo-Saxon point of view, cannot fail to be of interest to those of us who dwell in the Delta of the Ganges.

In my search it occurred to me that it might be of more than ordinary interest to observe, from an expert point of view, the references in the Rabbinical writings to gynæcology and obstetrics, and to this end I have used the Moffat Translation, the Revised Version, and the Douay Authorised Translation.

I do not intend to stray far outside the path of my title, but, perhaps it may entertain those of you who follow work at the Tropical School of Medicine to study that wonderful description of bacillary dysentery in the Second Book of Chronicles, Ch. 21, v. 15 and 19, and then to pass on to the picture of the oncoming of the monsoon in the First Book of Kings, Ch. 18, v. 43-45.

STERILITY.

Throughout the Old and New Testaments there are multiple references bearing on the psychological importance of the possession of children, for children are regarded as Divine gifts, *vide*, Gen. Ch. 4, v. 1; and Ch. 33, v. 5; and Ps. 127, v. 3.

This is a natural conclusion in a developing country where more hands meant better crops, and especially in the case of weak tribes, in which man-power was much needed for continual wars.

It is not surprising, therefore, that barrenness is looked upon as a reproach, thus Sarah was despised by Hagar, her handmaid, in Gen. Ch. 16, v. 4, for Sarah was primarily sterile and only later conceived after a long period of amenorrhoea, *vide*, Gen. Ch. 18, v. 11.

Again, Rachael in Gen. Ch. 30, v. 1, through envy of Leah cried, "give me a child or else I die"; and in I Sam. Ch. 1, v. 6, we find Hannah's rival taunting her because the Lord "hath shut up her womb." In St. Luke Ch. 1, v. 25, it says that "Elizabeth rejoiced when the Lord took away her reproach among men"; and again in St. John, Ch. 16, v. 21, our Lord refers to "the joy of a woman at the birth of a man child into the world."

It is of considerable interest to find such classical examples of elderly primiparæ and note that presumably in those times these children were born without trouble to either mother or child; whereas to-day circumstances and experience so frequently indicate Cæsarean section for such cases. The elderly primiparæ mentioned are Sarah, (Gen. Ch. 21, v. 2,) who bore Isaac; Manoh's wife, (Judges 13, v. 24,) who bore Samson; Hannah, (I, Sam Ch. 1, v. 20), who bore Samuel; the Shulamite woman (II, Kings, Ch. 4, v. 17); and Elizabeth, (St. Luke Ch. 1, v. 36) who bore John, and in whom "quickening" at about the 20th week is first mentioned.

In connexion with sterility it may here not be out of place to enquire how it is that the Jews, despite all persecution, are now, as then, the most prolific people in the world. From a Biblical point of view there would appear to be two reasons, which, in those days were empirical, based on minute observations of the priests, but to-day are proven to have a scientific explanation.

The first reason is in the diet. This consisted of substances perfect in A, B, C, and E vitamins, for instance, read David's entertainment (II Sam. Ch. 17, v. 28) of "wheat, barley and meal, and parched corn, beans and lentils and olives, honey and butter and sheep and cheese of kine"; and that of Solomon in I Kings, Ch. 4, v. 22, which is much the same, included "fatted fowl and fatted oxen."

It is not necessary to refer to the countless enumeration of fruits and vegetables including cucumbers, melons, leeks, onions, and garlic, though as a sidelight it is perhaps interesting, in view of the modern sugar fermentation, that "a

lump of figs" was prescribed by Isaiah as "a plaster" for Hezekiah's boil, (II Kings Ch. 20, v. 7.).

From the above diet it would therefore seem that the work of Mellanby, McCarrison, Plimmer, and Marshall in Great Britain, and Dickinson in America, on the effects of food on reproduction and health were empirically anticipated by the patriarchs; and that the maxim "the vitamins are to the endocrines what the endocrines are to the economy," was instinctively realized by the Jewish people. One must, however, admit from the story of Rachael and Leah that superstition or medicinal properties apparently attached to mandrakes, (love-apples in Moffat), for in Gen. Ch. 30, v. 14, it is written "Reuben going out at the time of the wheat harvest found mandrakes which he brought to his mother Leah, and Rachael said, 'Give me part of thy son's mandrakes, and Jacob slept with Leah that night and she conceived'; and later also Rachael conceived,"—Mandrake is *Mandragora autumnalis* (Solanaceæ), and is an antispasmodic.

The second reason for the multiplication of the people of Israel is to be found in the Book of Leviticus, in which those rules for coitus are laid down which are of such extreme interest in view of the recent work of Wilfred Shaw, Novak, and others on ovulation; for it has been proved that ovulation does not occur until the 13th to the 17th day of the menstrual cycle, counting the cycle as beginning on the first day of the period. Now coitus is forbidden to orthodox Jews before eight days after the last day of the period, that is, coitus is not permitted until approximately the time of ovulation.

Moreover, with reference to the above rules as regards coitus, and menstruation, it is a remarkable fact that the orthodox Jewish woman is almost immune to cancer of the cervix uteri. Is this immunity the result of circumcision and therefore of greater cleanliness, or is it because their code permits no extraneous organisms to enter the vagina during the first eight days after the menstrual period—that is, during a time when the vagina is alkaline and its resistance to infection therefore least; for we now know that the acid protective flora of the vagina and cervix are not normally actively present until the seventh or eighth day following menstruation.

May one not therefore suggest that the ultra-microscopic organism of Gye and Barnard or the "individual potential virus" is neutralized in the orthodox Jewess by these rules for coitus laid down in the Mosaic Laws; for one would expect in a community in which large families are the rule rather than the exception, that cancer of the cervix uteri would be particularly common.

Moreover, in a people bound by such laws of cleanliness, it is not surprising to find that there are very strict prophylactic rules for prevention of infection in women; for instance, in Lev. Ch. 15, it is laid down that "the man that hath an issue of seed shall be unclean and then shall he

be judged subject to this evil when a filthy humour at every moment cleaveth to his flesh and gathereth there. If he who suffereth this disease be healed, he shall number seven days after his cleansing and having washed his clothes and all his body in living water he shall be clean." It is probable that this is the first mention of venereal infection in the Bible.

LABOUR.

Considering the family character of the Biblical narrative, it is perhaps surprising that there are not more accounts of abnormal parturition. A possible explanation of this fact may be that, with a healthy population and healthy diet, difficult labour did not occur very often. There are, however, references to traumatic miscarriage and abortion in Ex. Ch. 21, v. 22, and Num. Ch. 12, v. 12.

Labour was in the hands of midwives probably of the Sarah Gamp or *Sage femme* type, who did little beyond ironing the vagina and giving kindly advice; though it is obvious from the reference (Job. Ch. 26, v. 13) "his obstetric hand brought forth the winding serpent," that operative midwifery, probably version, was practised.

In Ex. Ch. 1, v. 15, it is written "and the King of Egypt spoke to the midwives of the Hebrews, commanding them that, when they attended the Hebrew women and saw them on the birth-stool they were to kill the child if a male and let it live if a girl"; and when they did not obey him they answered the King's enquiry by saying, "because the Hebrew women are not like the Egyptian women, they are brisk creatures and delivered before ever a midwife reaches them." The Revised Version translates this passage "the Hebrew women are skilful in the office of a midwife and are delivered before we come to them."—the "B.B.A." (born before arrival) of the modern student.

It is, however, pleasing to recognize that then, as now, a good midwife was treasured and flourished exceedingly, for one reads "God dealt well with the midwives and built them houses."

The meaning of the "birth-stool" is of interest, for it would seem that postural treatment of labour cases was regularly practised by the ancients. Indeed, the squatting position is that used to-day in the East for a hard labour, and there is no doubt of its efficacy as I have myself noted in right occipito-posterior cases. The purchase given to the patient by her arms round her knees in the squatting position promotes flexion, rotation, and descent of the head, and this presumably is the meaning of Gen. Ch. 30, v. 3, "go in unto her that she may bear upon my knees," and Job Ch. 3, v. 12, "why received upon the knees." For then, as now, among many primitive people the travelling mother was placed either squatting between the knees of the midwife, or in a kneeling position bending over her thighs.

The birth-stool, or *Kreisstuhl*, as the Germans call it, can be seen in France and Germany to-day, just as it can be seen in parts of India, Japan and China, and it certainly has mechanical if not æsthetic advantages.

In a work published in 1637 called "The Expert Midwife" by James Rueff, we have an exposition of the use of this stool, which is of historical interest. "Let the stool be made compasswise, under-propped with four feet, the stay of it behind bending backward, hollow in the midst, covered with a black cloth underneath, hanging down to the ground, by that means the labouring woman may be covered, and the other women sometimes apply their hands in any place, if necessity require. Let the stool be furnished and covered with many cloths and colours at the back and other parts, that the labouring woman receive no hurt of the infant anywhere, strongly kicking and striving because of the pains, stirrings and motions of the mother. After the labouring woman be placed in her chair about to be delivered, the midwife shall place one woman behind her back who may gently hold the labouring woman, taking her by both the arms, and if need be, the pains waxing grievous may stroke and press down the womb, and may somewhat drive and depress the infant downwards. But let her place other two by her sides which may both, with good words, encourage and comfort the labouring woman, and also be ready to help and put to their hand at any time. This being done, let the midwife herself sit stooping forward before the labouring woman and let her anoint her own hands and womb of the labouring woman with oil of lilies, of sweet almonds, and the grease of a hen mingled and tempered together. For to do this doth profit and help them very much which are gross and fat and them whose secret parts are strict and narrow, and likewise them who have the mouth of the matrix dry, and such women as are in labour with their first child." From this description we may picture the use of the birth-stool in the days of Moses.

The first record of a midwife attendance is in Gen. Ch. 38, v. 27, and is of great interest, for it represents classical treatment, and is the first published case of spontaneous evolution with live uniovular twins and ruptured amniotic sac, or sacs, which according to Whitridge Williams, is very rare, only 44 cases being on record. It is interesting to note that Viardel in the 17th century first observed this and stated that, when twins were of the same sex they were usually enclosed in a single amnion, whereas twins of different sexes were separated by a partition wall; he expressed the belief that Providence took this means of guarding their morals *in utero*!

The passage in the Bible referred to above, runs "Thamar appeared to have a big belly, and when she was ready to be brought to bed there appeared twins in her womb, and, in the very delivery of the infants, one put forth a hand

whereon the midwife tied a scarlet thread, saying, *this shall come forth the first*; but he, drawing back his hand, the other came forth, and the woman said why is the partition divided for three, and therefore called his name Phares, afterwards his brother came out on whose hand was the scarlet thread, and she called his name *Zara*." This case is of additional interest for it might appear from another interpretation of the text that this is the first recorded case of complete rupture of the perineum, and as there is no further mention of Thamar it is probable she died of puerperal sepsis.

There is only one other reference to twin labour and it gives one food for thought. It is in Gen. Ch. 25, v. 21-26, "and Isaac besought the Lord for his wife because she was barren, and He heard him and made Rebecca to conceive, and the children struggled in her womb and she said, 'If it were to be so with me what need is there to conceive.'" The meaning of this is, that miscarriage or premature labour threatened, for obviously it was recognized that tumultuous movements of the fœtus with or without a "big belly" frequently anticipated premature labour or death of the fœtus. "And she went to consult the Lord and when her time was come to be delivered, behold twins were in her womb, he that came forth first was red and hairy like a garment and his name was called Esau, and immediately the other coming forth held his brother's foot in his hand and therefore he was called Jacob." One may therefore presume from this that the children were uniovular twins, somewhat premature, and not of great size seeing that Rebecca was a primipara and had been married some time.

I have often wondered if Esau was a freak of atavism, but in the light of modern endocrinology I am inclined to think that here we have the first traditional examples of hyper- and hypoadrenalism; for we read that "Esau became a mighty hunter and a man of the field," whereas "Jacob was a smooth man and dwelt in tents," what in the East to-day would be called a Babu.

In II Kings, Ch. 19, v. 3, it is obvious that uterine inertia was recognized as of grave omen to the women in labour, for one reads "This day is a day of tribulation and of rebuke, the children are come to the birth and the woman in travail had not strength;" and again in Jer. Ch. 15, v. 9, "she hath borne seven, is become weak and her soul hath fainted away."

In Gen. Ch. 35, v. 16, we have the tragic account of the death of Rachael. "And Jacob moved on in the springtime, and was still some distance from Ephrath when Rachael felt the pains of child-birth, she had hard labour, but in the midst of her hard labour, the midwife said unto her, 'Fear not, you are going to have another son,' and when her soul was departing for pain, and death was now at hand, she called the name of her son Benoni—the son of my pain." One wonders much what her death was due to,

for assuredly it must have been a bitter blow to Jacob after his long wait for Rachael. It is, I think, obvious that the presentation was normal, but the fact that labour came on while they were "on trek," suggests prematurity, for the "chosen people" do not travel during the tenth lunar month. Possibly placenta prævia, morbus cordis, or toxæmia of pregnancy caused the unexpected onset of labour; but if eclamptic convulsions had occurred they would have been mentioned. It is not improbable that a fibroid tumour of the uterus with the pregnancy may have been the cause, for in Gen. Ch. 31, v. 35, the text suggests that Rachael suffered from old standing dysmenorrhœa and menorrhagia; for Rachael states "let not my lord be angry with me that I cannot rise up before him, because it has now happened to me according to the custom of women."

In I Samuel, Ch. 4, v. 19, there is a wonderful clinical picture of precipitate labour, associated with cardiac shock and fatal syncope, the result of sudden emptying of a big uterus; "And the wife of Phinehas was big with child, and near her time, and hearing the news that the Ark of God was taken and her father-in-law and her husband were dead, she bowed herself and fell in labour, for her pains came upon her on a sudden, and when she was on the point of death they that stood about her, said to her, 'fear not for thou hast borne a son,' but she answered them not nor gave heed to them." This wonderfully graphic description cannot fail to appeal to any obstetrician who has seen a case of cardiac shock, colossal post-partum hæmorrhage, or acute inversion of the uterus.

There is a curiously sinister and graphic description in Num. Ch. 5, v. 21, which can be interpreted in various ways, but I think the probabilities are in favour of general peritonitis, or acute hydramnios, for it is written, "if thou hast gone aside from thy husband and art defiled, the Lord make thee accursed, and an example for all among His people. May He make thy thigh to rot, and may thy belly swell and burst asunder. Let the cursed waters enter into thy belly, and may thy womb swell."

In Job Ch. 38, v. 8, we find a picturesque description of sudden rupture of the membranes, which will remind many students of their days 'on the district.' The passage runs, "who shut up the sea with doors when it broke forth as issuing out of the womb."

Finally, it is interesting to note that there are no references to the pangs of child-birth being pleasurable, or easy. Among other quotations we have that of Gen. Ch. 3, v. 16, "I will make child-birth a sore pain for you, you shall have pangs in bearing, yet you shall crave to have your husband and he shall master you."

Women of Great Britain have to thank Queen Victoria who was the first to popularize the use of anæsthetics during child-birth, and it cannot fail to be a matter of pride that the original chemical discoverer of chloroform, (though it was first used by Sir James Simpson) was a member

of this learned Society and lived here. I refer, of course, to David Woldie whose honoured bust is in your Hall.

PUERPERIUM.

It is curious to note that, beyond the immediate death of Rachael, and the wife to Phinehas, and presumably Thamar, there are no references to anything that would indicate puerperal sepsis, although, as I have previously pointed out, the "obstetric hand" of Job. Ch. 26, v. 13, would appear to suggest recognition of operative or manipulative midwifery.

Perhaps it was of such that it is written in Ecclesiasticus, "Honour the physician for the need thou hast of him, for the Most High hath created him. The skill of the physician shall lift up his head, and in the sight of great men he shall be praised." It is not impossible, however, that the son of Sirach inferred the meddlesome midwife when he wrote the bathos, "He that sinneth in the sight of his Maker shall fall into the hands of the physician." But all the same, worthy or unworthy, a physician was entitled to his expenses or fees! vide Ex. Ch. 21, v. 19.

In the case of a male birth the puerperium lasted 33 days and coitus was forbidden before that date. In the case of a female child 66 days had to elapse before purification or coitus. No adequate explanation for this differentiation can be put forward.

GYNÆCOLOGY.

There are not many references to gynæcology, though there are very exact rules, regulations, and medico-legal enactments as regards rape, incest, consanguineous marriages and prostitution. One of the earliest and most characteristic stories of rape is in Gen. Ch. 34, with its tragically amusing sequel in verse 25, for this is the first reference to minor clinical surgery in the Bible; "The men of Shechem had consented to be circumcised in order to legalise the marriage of their chief to Dinah, whom he greatly loving had ravished": and it was written "The circumcision was done on all the men, and behold the third day when the pain of the wound was greatest, the sons of Jacob entered boldly into the city and slew them."

Apart from the tragic side of the vengeance, this incident is of great gynæcological and sociological importance, for it creates a new point of view as regards women in ancient times. Throughout the world up till then, the neolithic idea of women, as so much property, existed; and compensation for injury to such property was all that was demanded. Here, however, we find that the idea of purity has entered the Hebrew mind, and a law is made imposing the death penalty for infidelity in marriage or for the seduction of an affianced girl. Moreover, the penalty of marriage is created, for a man, seducing an affianced girl, is compelled to pay her price and to take her for wife. From this we must

assume that here we see the dawn of emancipation for women, for up till then they were steeped in an inferiority complex.

In the days of the Patriarchs a woman did not exist until she was married, and even then we have the instance of the wife of Joakim carrying the load of inferiority which was hers as a girl, though she was innocent of the charge of infidelity made against her.

The story of Judith and Holofernes indicates, perhaps, the degree of emancipation reached; and for those who are students of Schopenhauer, Otto Weiniger, or Ludovici, it will not come as a surprise that 2500 years ago there was shown for women a great contempt as well as a great respect. We find Ecclesiasticus urging "man not to be jealous of his wife but to keep his soul from her." "He is to beware of a woman who sings, he is to turn away his eyes from a beautiful woman, because beauty is a snare. He is not to look upon another man's wife. He is to fear wine and woman, for a woman is either a reward or a punishment."

The sin of Onan (Gen. Ch. 38, v. 10,) would appear to foreshadow one of the present modes of birth control, and to indicate "withdrawal." There is nothing in any of the texts to suggest that masturbation is inferred. It is obvious that such a method was considered an abomination, and was looked upon as unhealthy, as indeed it is for both parties. Moreover, up to the present day this and all such methods are taboo among orthodox Jews, wherefore they multiply.

Lastly, there is the well-known incident in St. Mark Ch. 5, v. 25, which is so invariably quoted by Christian Scientists: "And a woman who was under an issue of blood 12 years, and had suffered many things from many physicians, and had spent all that she had, and was nothing the better but rather the worse, when she heard of Jesus, came in the crowd behind Him and touched His garment, for she said, if I shall touch but His garment I shall be whole. And forthwith the fountain of her blood was dried up and she felt in her body that she was healed of the evil. And He said to her, 'Daughter, thy faith hath made thee whole, go in peace and be thou whole of thy disease'."

"Well ordered words are as the honeycomb, sweet to the soul, and health to the bones, and good instruction shall give grace."

SPECIAL REPORT.

THE SEVENTH CONGRESS OF THE FAR EASTERN ASSOCIATION OF TROPICAL MEDICINE, held at Calcutta from Dec. 5th to Dec. 10th, 1928.

(PART II.)

(Continued from p. 148 of our issue for March 1928.)

DYSENTERY. SPRUE. BACTERIOPHAGE.

THESE subjects were dealt with in Section III of the Congress on December 7th at the morning and after-

noon sessions. The Section was presided over by Professor K. Shiga of Japan, of Shiga bacillus fame.

The Section was opened with a paper by Mr. A. C. Ukil, M.B., on the dysenteries of Bengal. On an analysis of 1,500 cases observed he stated that bacillary dysentery was commoner than amœbic in Bengal; that organisms of the *Salmonella* group were responsible for some cases; that cultural studies of the intestinal contents of flies showed that they might prove to be of importance in the ætiology of dysentery; whilst the role of the intestinal flagellate protozoa was discussed. During the discussion which followed this paper various speakers emphasized that bacillary dysentery is far more common in India than amœbic, the proportion of the former to the total number of cases being given by various speakers at from 66 to 90 per cent.

A joint paper on recent work at Parel on sprue by Lieut.-Col. F. P. Mackie, O.B.E., I.M.S. and Dr. Hamilton Fairley was read by the former author. These workers had found *Monilia psilosis* in cases of diarrhœa which were not sprue, and had found it very toxic to rabbits. Study of the liver function in sprue by the lævulose tolerance and other tests had shown that in sprue the liver function is not at fault. There is but little evidence of any serious derangement of the pancreas. A study of the morbid anatomy and histology of the disease does not show any pathognomonic lesions, and it is difficult to say whether the general mucosal atrophy present in the gut is the cause or the result of the disease. The changes in the bone-marrow bear out the contention that the anemia of sprue is of aplastic type. The commonest micro-organism isolated from the stools is of *B. morgani* type, whilst hæmolytic bacteria are common and may have something to do with the anemia of the disease. The authors insist that sprue is a clinical entity quite distinct from pernicious anemia. The blood picture of the two diseases is also quite different.

Three papers dealing with the bacteriophage were read by Professor d'Herelle, whose work on this subject is so well known, and were listened to with profound interest. The bacteriophage, he claimed, is a principle which produces the dissolution of bacterial cells and reproduces itself in the course of this dissolving process. This principle is present in the intestine of every man and animal; in normal individuals it develops upon saprophytic intestinal bacteria. During recovery from a bacterial disease, a bacteriophage principle, capable of dissolving the bacterial agent of the disease, is present in the intestine of the convalescent and even in certain organs.

During the last six years, several hundreds of papers have been published on the question of the nature of the bacteriophage. This question is a very important one, for it has a repercussion on the study of a whole series of phenomena which constitutes bacteriophagy *in vitro* and *in vivo*, i.e., the experimental phenomenon of bacteriophagy and the natural process of bacteriophagy which occurs in the body in the course of infectious disease.

He had brought out a whole series of experiments (since confirmed by several authors), which show that the bacteriophage is composed of filter passing corpuscles; that these corpuscles are autonomous and possess their own properties, entirely independent from the bacteria at the expense of which they reproduce themselves; that these corpuscles possess the powers of assimilation and adaptation. Those various properties, autonomy, assimilation and adaptation, constituting the criteria of life, every being which possesses them is necessarily living "by definition."

The bacteriophage then is a filter passing parasite of bacteria, *Protobios bacteriophagus* d'Herelle, 1918, and the phenomenon of bacteriophagy in reality is the result of an infectious disease that prevails amongst bacteria.

In his second paper Dr. d'Herelle dealt with the relationship of the bacteriophage to epidemic intestinal diseases.

In the infectious intestinal diseases of man and animals, the end result, recovery or death, is intimately

associated with the behaviour of the intestinal bacteriophage.

In normal individuals, bacteriophage lives upon saprophytic intestinal bacteria. By a process of adaptation (experimentally demonstrable *in vitro*), which is more or less rapid according to surrounding circumstances, bacteriophage is able to parasitize any invading bacteria.

Experiments show that the patient invariably succumbs when the adaptation is lacking. In case of recovery, the improvement begins from the time when the bacteriophage isolated from the stools of the patient is capable of producing complete bacteriophagy *in vitro*.

The importance of the behaviour of the bacteriophage upon the course of an epidemic is as great as it is upon the process of the recovery.

At the beginning of an epidemic there are disseminated into the environment the pathogenic bacteria; this is the period of the propagation of the disease. Then from the first convalescent, there are disseminated bacteriophages which have acquired the power of killing and dissolving the pathogenic bacteria in his intestine. From this time more and more patients recover, bacteriophages become more and more disseminated, and the epidemic declines, finally to cease when "contamination" by bacteriophage becomes general.

Recovery and immunity are contagious in the same way and by the same means as infectious disease itself.

In his third paper, Dr. d'Herelle dealt with the treatment of cholera and bacillary dysentery by bacteriophage.

"In a preceding paper, I have pointed out that observations and experiments show that the behaviour of the bacteriophage is intimately related to the natural process of the recovery as well to the stopping of the epidemics. The best way to verify the truth of such a statement is to realize cross experiments, i.e., to reproduce both processes experimentally by employing cultures of bacteriophages.

In relation to bacillary dysentery, I treated in 1919 several cases of Shiga and Flexner dysenteries, giving 2 c.c. of a culture of a potent bacteriophage, to be taken by mouth. In every case all symptoms definitively disappeared within 24 hours, whatever the gravity might be. Since then bacteriophage treatment has been widely employed in Brazil and in the Sudan, where thousands of cases have been treated, and my first statement has been entirely confirmed.

I must strongly warn experimenters that cultures of *vacak* bacteriophages are entirely useless for the purpose of treatment.

In the course of the present year, thanks to the Indian Research Fund Association, and with the collaboration of Major Malone, I.M.S. and Dr. Lahiri, I have been able to make extensive researches in relation to cholera. In the great majority of cases the result of the bacteriophage treatment in cholera has been fully efficient.

We have also tried the stopping of village epidemics by spreading over potent cholera bacteriophages into the environment. To that purpose we have added 50 c.c. of a selected bacteriophage culture in the wells supplying the infected area. The first results have been extremely promising."

GENERAL MEDICINE.*

In this Section the session was opened by a paper by Lieut.-Col. F. A. F. Barnardo, C.I.E., C.B.E., I.M.S. on the importance of mixed infections in the practice of medicine in the tropics. He dealt with such conditions as streptococcal septicæmia as a complication of typhoid fever, with kala-azar as a sequel to enteric fever, and with ankylostomiasis and latent malaria as complications of many tropical diseases. The importance of recognising that a patient in the tropics is almost always suffering not only from a primary disease, but from other secondary infections or associated infections

which may complicate the clinical picture is very great.

There was considerable discussion after this paper, the various speakers all laying emphasis on the necessity for a general assessment of the various infections from which the patient was suffering, and for a due weighing of their importance in his clinical state.

This was followed by a paper by Lieut.-Col. C. A. Sprawson, C.I.E., I.M.S. on disseminated sclerosis in India. He claimed that the disease is non-existent or almost non-existent among Indians, and also in Mesopotamia, and discussed the reasons for this. In the subsequent discussion various speakers questioned this statement. Major V. G. F. Labernadie of Pondicherry followed with two short papers, and then Dr. U. P. Basu read a very informative paper on the scope of digitalis in the tropical heart of Bengal, illustrated by lantern slides. He first described the results of complete physical and auscultatory examination of 50 healthy adult Bengalis and 25 similar Europeans, with illustrative blood pressure tracings, radiographs of the heart, and electro-cardiograms. He then described the morbid anatomy and histo-pathology of a series of 50 hearts of persons between 25 and 35 years of age who had died suddenly as the result of accident. Under diseased conditions he contrasted the commoner cardiac conditions found in Indians in Calcutta with those for Europeans in Europe as seen in the cardiac clinics in London; also the cardiac complications of the common fevers and other common diseases of Bengal.

At the afternoon session Dr. J. W. Tomb, O.B.E. read a paper on the incidence and significance of certain clinical signs, such as intestinal cramp, vomiting antecedent to purging, and blood-stained stools in the diagnosis of cholera and its treatment. Rai Lal Behari Ganguly Bahadur then read a paper dealing with the present day treatment of cholera, based upon his many years' extensive experience in the treatment of the disease at the Campbell Hospital, Calcutta. In general treatment with hypertonic salines was of special value, and several of the newly introduced remedies, such as the essential oils, did not seem to improve matters. His paper was followed by a short discussion.

The session on Tuesday, Dec. 6th, was devoted to a discussion on diabetes and it was resolved (with the consent of the chairman) to divide the discussion into two parts, Part I dealing with the bio-chemical aspects, and Part II dealing with the clinical side.

The opening paper in Part I was contributed by Major H. Stott, I.M.S. (Lucknow). The speaker remarked that the race factor *per se* had no influence on the blood-sugar level. He pointed out that though the normal fasting blood-sugar level in Indians was usually higher than in Europeans in an equal state of health, experience gained in the war had demonstrated that healthy Indian sepoys on a mixed diet and doing hard physical exercise had a fasting blood-sugar level similar to that of Europeans. His opinion was that a fasting blood-sugar level above 0.15 per cent. should be considered abnormal. The speaker next discussed the question whether the so-called "alimentary" glycosuria could be separated off from the true pancreatic diabetes. He considered that from the point of view of blood-sugar estimations such a separation could not be effected though it might be possible clinically.

The second paper in this section was read by Capt. S. L. Bhatia (Bombay). He gave an account of a series of blood-sugar estimations on apparently normal Indians in Bombay. His conclusions were that the average fasting level of blood-sugar was a little higher and the sugar tolerance a little poorer in persons who lived on a purely vegetarian diet rich in carbohydrates than in those who lived on a mixed diet of meat and vegetables. He said that glycosuria often followed the administration of 50 grammes of sugar in some of these apparently normal vegetarian Indians, and he believed that it was the "alimentary" type and was mainly dietetic in origin.

Dr. J. P. Bose (Calcutta) was then invited to discuss. He agreed with Major Stott that race *per se* had no influence on the blood-sugar level. The fasting level

* Report by Dr. J. M. Henderson, Calcutta School of Tropical Medicine.

of blood-sugar may vary, though slightly, due to habits of a particular race. For instance a normal Bengali, living on mixed diet and doing ordinary physical exercise usually has a blood-sugar quite comparable to the European standard (average 0.100 per cent). On the other hand, the fat indolent type of Bengalis may show a fasting blood-sugar level of 0.12 per cent. In his opinion persons having a fasting blood-sugar level over 0.13 per cent. should be considered abnormal and should be classed under "potential diabetics."

The speaker did not agree with Capt. Bhatia's findings about the sugar tolerance in apparently normal vegetarian Indians. He considers that to have hyperglycaemia over the kidney threshold and to pass sugar in the urine after a test meal of glucose is distinctly pathological. He objected to the use of the term "alimentary glycosuria." He remarked that in a normal healthy person it is impossible to induce the blood-sugar to go over the renal threshold however large an amount of sugar be given.

Major S. S. Sokhey, I.M.S. (Bombay) thought that the "respiratory quotient" should receive more attention in investigating cases of diabetes.

PART II.

Major Stott then read the second part of the opening paper. He dealt first of all with the frequency of diabetes in India. The type of diabetes met with in India is usually of a rather chronic nature and is attributable largely to dietetic and social conditions. With regard to the more acute type of diabetes (commonly met with in young people) the speaker has found that no fewer than 50 per cent. of his cases in patients under 25 years of age showed a positive Wassermann reaction. Major Stott then considered the question of the renal threshold level for excretion of sugar and pointed out that a "high" renal threshold sometimes occurs in advanced cases of diabetes and in chronic intestinal nephritis. He divided the cases of chronic (dietetic) diabetes into 4 stages; (a) stage of hyperglycaemia; (b) stage of intermittent glycosuria; (c) stage of chronic glycosuria; (d) terminal stage with complications. The speaker concluded his paper by showing a series of lantern slides illustrative of typical cases treated in hospital at Lucknow.

The second paper in this section was read by Dr. M. M. Dutt (Calcutta) who gave an account of his experience of diabetes in Bengal. The speaker believed that infection plays a very important part in the etiology of diabetes. He deprecated the practice of "starvation treatment" in the disease and outlined a regime which he had employed for some time with considerable success, which consisted of supplying to the patient, sufficient calories for his daily requirements.

Lieut.-Col. J. D. Sandes, I.M.S. (Calcutta) was of opinion that even now the treatment of diabetes could not be deemed particularly satisfactory. The original "Allen treatment" had fallen far short of expectations and had to be considerably modified. He gave a brief outline of his clinical experience with diabetes.

Lieut.-Col. C. A. Sprawson, I.M.S. dealt with the question of diabetes complicated by other diseases like nephritis, syphilis and tuberculosis, and pointed out the necessity of treating such diseases along with diabetes. Such complications frequently obscure the clinical picture, e.g., in diabetes complicated by nephritis the patient dies of uremia, and not of diabetic coma.

In the discussion which ensued various points arose; several speakers expressed surprise at the high percentage of positive Wassermann reactions found by Major Stott in his young diabetics and enquired regarding the general consensus of opinion regarding syphilis as a predisposing cause of diabetes. Dr. Bose remarked that only 2.5 per cent. of his cases gave a positive Wassermann reaction.

A member advocated the use of an extract from the leaves of the plant *Gymnema sylvestre* in diabetes. Major Sokhey and Dr. Bose gave their experiences with this line of treatment. They had formed the opinion that it was quite useless.

Major Stott having briefly replied, the proceedings of the Section terminated.

STATE AND PREVENTATIVE MEDICINE.

This Section was opened with a paper by Colonel J. D. Graham, C.I.E., I.M.S., Public Health Commissioner with the Government of India, on the international aspects of disease with special reference to quarantine. He reviewed briefly the various factors leading up to the present co-ordination of different national and international activities directed towards a more accurate knowledge of world-epidemiological conditions, and the simplification of quarantine. The procedure of the Office Internationale d'Hygiene Publique and of the League of Nations Health Section was outlined, and their relationship with India discussed. Dr. McVail contributed a paper giving an account of quarantine conditions in the port of Calcutta.

A paper in this Section which aroused considerable discussion was one by Lieut. Col. A. J. H. Russell, C.B.E., I.M.S. on the problems of population and public health in India.

He referred to the population curves devised by Professor Raymond Pearl, and said that he had applied the methods suggested by Professor Pearl to the population of India as a whole, and to the populations of various provinces and towns, and come to the conclusion that in India populations were now tending to approach their "constant" maximum point. He deduced from this that there had been already serious overcrowding in India, and advocated a bettering of the stock by more attention being paid to the normal, clever and promising individuals.

These views were combated by Col. Gill and Col. Bisset who pointed out that in the past public health measures had begun by attention being paid to the poor and the diseased and that the betterment of the race had undoubtedly resulted from an application of these principles. They also pointed out that Col. Russell's mathematical conclusions were based on the assumption of certain "constants" and that these "constants" might easily vary from year to year and specially so in a country like India, where conditions were at present unstable, and were likely to be so for a long time.

Col. Gill held that an increase of population, far from necessarily being an evil, might stimulate individuals and nations to developments in the science and art of food production. The questions underlying these problems, he said, were too large, and too fundamental to be adequately discussed within the short time at their disposal. They were nevertheless of extraordinary importance, not only to medical men, but also to administrators and statesmen.

Dr. Crow, Port Health Officer, Rangoon read a paper on de-ratting of ships, in which he discussed the relative value and cost of different methods. The cost of fumigating a vessel falls on the shipping company concerned, and "grape shot methods" of fumigation are costly and lack precision. If the number of rats destroyed is taken as a criterion of rat infestation, then fumigation, its cost, and the delay to the ship is not justified, particularly as trapping failed to elicit any undue rat population in some of the vessels. The cost per rat killed by fumigation might be anything from 8 annas to Rs. 195. Rat trapping and rat searching can always be relied upon to give an index of the numbers of rats on any one vessel, and to indicate whether fumigation is or is not advisable. If the store-room, the galley, and the crew's quarters are made as rat-proof as possible, there is a considerable diminution in the number of rats on the vessel. On the other hand rat-proofing in the tropics is apt to interfere with the necessary ventilation.

Dr. J. N. Leitch gave an account of a health campaign among 7,000 tea garden coolies in Assam. The following is a summary of his paper:

An attempt has been made to evaluate the various factors in disease prevention, as experienced in a health

campaign extending over some three years, and involving about 7,000 tea garden coolies.

The initial difficulties were threefold. Firstly, the hospital records had not been kept on any system, so that no useful information could be obtained from them. Statistics were incomplete and misleading.

Secondly, different methods prevailed on different gardens, involving all dealings with disease and sanitation. These led to confusion and there was no basis on which results could be compared.

Thirdly, there was no standard of comparison, such as normal weight, height, and general physical measurements, as European tables are not applicable to such a population.

An attempt was made to overcome these difficulties. The sick registers were revised, and a nomenclature of diseases insisted on. A monthly health return form was adopted and has since been in regular use. A medical history sheet was elaborated to record all points of importance in logical order and eliminate the personal element as far as possible. A scheme of standard treatments was drawn up, the principles of which were insisted on, so as to compare the results obtained.

By special parades extending over some three months, the whole population underwent a thorough physical examination, the results of which were recorded and classified. Treatment followed where necessary. A temporary laboratory was fixed up to help with the pathological work involved. Each illness has since been entered on to the patient's history sheet.

Attention was then directed to buildings and sanitation. The lines in which the coolies lived were in some cases irregular, difficult to drain, and dilapidated. Water-supply was crude and there was no means to prevent pollution. Sanitary measures consisted in a clean-up once a year only. Latrines scarcely existed and faecal infection of the soil was heavy. These points were illustrated by lantern slides, and showed the reconstruction which is now going on to remedy them.

Other measures include emergency treatment boxes on all out-gardens. Inspection of coolies is made fortnightly on pay days, and there is a house to house inspection of the lines daily. Carriers of disease are detected whenever possible and put under treatment. Fly and mosquito campaigns are going on, sanitary gangs are working in each line. Clinics have been started for child welfare, venereal diseases, leprosy and kala-azar. Weekly lectures on medical subjects are given to the hospital staffs. Health demonstrations aided by coloured posters are given to the coolies.

These activities are illustrated where possible, and details are given as to their results.

The present hospitals are quite unsuitable and inadequate. Plans are shown of the new ones now in course of erection and these are explained. The proposed administration of these hospitals is considered in detail. At present the patient's relatives are given leave to look after him, and this often results in very bad nursing and the giving of unsuitable food. The wards of the new hospitals are very much larger than those of the old, and it is proposed to have a trained attendant on duty night and day in charge of each. Accommodation is arranged for a pathological laboratory, an operating theatre, and a lying-in ward. A separate outpatient block is provided so as to keep the main hospital as clean and quiet as possible.

Results obtained to the date of writing are given.

Smallpox, of which there were always odd cases and occasional severe epidemics, has been completely abolished. The two or three cases occurring during the last year were strangers from surrounding villages, who came into our lines. All our own coolies have been vaccinated within the last 18 months.

Malaria has been reduced considerably, dysentery is much less than before, cholera is almost unknown. Other diseases are also decreasing as shown by the tables given. The birth-rate is rising considerably. There is a decrease in the death-rate of working coolies, but an increase in that of young children and of old people.

This is only apparent and is due to the more careful keeping of records.

The conclusions to be drawn from this work are as follows:

To prevent disease, no one method is adequate, but every method must be combined and persisted in.

The most important factor is to assure a thorough cure of each patient, and for this "follow-up" treatment is necessary. This is impossible without keeping careful records. The elimination of "carriers" thus accomplished probably does more than anything else to reduce disease.

The second factor is a good water-supply and conservancy system. Apart from malaria, probably some 90 per cent. of sickness is due to this lack. Evidence is produced to show the ravages of bowel diseases and worm infestations.

The third factor is adequate housing and sanitation.

The fourth factor is a first-class hospital and full equipment. This will not show an effect on the sick rate as much as the former factors, but will very materially reduce the death-rate.

The cost of disease is enormous, necessitating as it does the recruiting of new labour to replace wastage, outgoings in sick pay and attendances, lack of labour just when most needed to assure a large crop. It would be no exaggeration to put this cost at Rs. 3 per head per year.

The cost of prevention is also great, but not nearly so great as the former. Re. 1 per head per year for 5 years, followed by 8 annas per head per year or even less for perpetuity would be adequate to obtain the desired results.

Much is being accomplished by individual effort in an isolated way all over the world. When will these efforts be combined under one *generalissimo*, not only to fight disease but the callous indifference which perpetuates it?

Major J. R. D. Webb, O.B.E., I.M.S., Medical Officer of Health, Simla, read a paper on the medical inspection of Indian school children at Simla. This was systematically instituted in September 1923.

Simla with its season population of about 45,000, collected within a restricted area, is perhaps particularly well situated for work of this nature. Until December 1924, only the primary classes of boys between the ages of 6 to 11 years were dealt with. The total number so handled was 731. In late 1924 the work was extended to all boys' schools at Simla, while in 1926 all girls attending schools came under medical supervision. At the present time it is estimated that there are about 2,500 boys and about 600 girls who are under regular medical inspection at the 27 schools in Simla. The cost is estimated at approximately one anna per child per mensem, excluding the cost for instruments, printing of stationery and medicines.

The system of medical inspection at Simla which is now in practice has been evolved by closely studying similar systems in other parts of the world.

The system embodies:—

(1) The medical inspection of each child once every two months, with a view to the prevention and cure of disease.

(2) The assured treatment of affected children.

(3) Reports of the above results, which are combined to form an annual report.

(4) A monthly inspection of school premises, followed by reports combined to form an annual report.

The Simla population is very largely a seasonal one, fluctuating with the change of Government office employees. Changes amongst the children we are dealing with are inevitable. This tends to retard the rapid and complete success of the work. The following are the results obtained during the past four years:—

During 1923-24, out of 731 boys examined, 67 per cent were referred for treatment at the first inspection, whereas this figure was reduced to 33.03 per cent by the end of 1924. As already stated, during 1923-24, only the primary classes at the boys' schools were dealt with, consequently these results do not direct comparison

with those of subsequent years. In 1925, 81 per cent. of the boys were referred for treatment at the first series of inspections, while by the end of the year, this figure was reduced to 30 per cent. In 1926, at the first series of inspections, 43 per cent. of the boys and 75 per cent. of the girls were referred for medical treatment, also 45 per cent. of the boys and girls were recommended for attention by the masters and mistresses for uncleanness and other minor conditions. By the end of the year, these figures were reduced to 15 per cent. of the boys and 43.2 of the girls requiring further recommendation for medical treatment, while 21 per cent. of boys and 20 per cent. of girls still required attention by the masters and mistresses. In 1927, at the first series of inspections, 39.6 per cent. of the boys and 63 per cent. of the girls were recommended for medical treatment while 44.7 per cent. of the boys and 37.3 per cent. of the girls required attention by masters and mistresses. Averages of height, weight and chest measurements for Simla school boys and girls of varying ages were prepared in 1925-26.

The boys and girls now attending the 27 schools at Simla are of good physique and they comply with the standards already referred to. These results have been achieved by constant medical supervision and treatment, together with a system of regularised exercise by a *games-for-all movement*, and with a scheme for the supply of midday meals for the children.

"Observations on the Activated Sludge Process in Calcutta" was the title of an interesting paper read by Lieut.-Col. A. D. Stewart, I.M.S., Calcutta School of Tropical Medicine in the Hygiene Section.

Col. Stewart began by stating that in India safety and freedom from nuisance and danger usually had to be subordinated to questions of expense. Large towns are comparatively few, and as it is only in these that enough money is available for modern sewerage systems, the mass of the country must for a long time put up with comparatively primitive methods of nightsoil disposal. That biological processes can be successfully worked in India had been demonstrated by the number of septic tanks and latrine installations in Bengal and elsewhere.

These were somewhat expensive, however, and it could not be said that they were free from nuisance. The activated sludge process, the newest of the biological processes, had so far given satisfactory results, and it was desirable that this process should be examined as much as possible under the varying conditions of Indian climates and circumstances.

Briefly, the process was one by which a sludge rich in purifying element was first prepared. This, mixed with raw sewage in the proportion of 10 to 15 per cent. of sludge, and aerated with agitation, should in the course of a few hours produce a fluid out of which the sludge settles quickly, leaving a supernatant fluid which is safe, aseptic and inoffensive.

The disposal of the sewage of Calcutta was at a critical stage of discussion at the moment, and for that reason it was desirable to ascertain if the Calcutta sewage lent itself to purification by this process.

After describing numerous experiments with the process recently carried out in Calcutta, Col. Stewart held that in view of the experiments Calcutta sewage at its outfall from the city could easily be purified with four hours aeration with an active sludge. It had to be remembered, he pointed out, that Calcutta sewage was comparatively weak and had undergone a certain amount of decomposition by the time it reached its outfall.

MATERNITY AND CHILD WELFARE.

In this Section the discussion was opened by Dr. Ruth Young of the Lady Chelmsford League in a paper on the organisation of child welfare work, and obstacles in its way. She emphasised the necessity for the co-ordination of voluntary and official child welfare organisations under the supreme control of the Director of Public Health in each Province, and the appointment of medical women with special aptitude for the work at the head of each centre.

The reduction of infantile mortality, Dr. Young pointed out, is a somewhat negative appeal, and nowadays it is realized that all the positive factors that encouraged health, *ipso facto* reduced infantile mortality, and that the net cost of child welfare work is much wider than was originally supposed. Its ramifications extend in many directions, for example, into the realm of general hygiene, the study of propaganda work and its psychology, and educational work among future mothers now girls at school.

Objections to child welfare work were still heard, though the opposition was, for the most part, simply inertia rather than positive action. In India the ordinary member of a municipality often enough said: "What is the good of this work? We cannot see that it achieves anything." The most thoughtful person said: "India is over-populated as it is. Why save more babies? Better let them die so that those which do survive may have a less bitter struggle for existence."

Neither of these points of view could survive if people comprehended the real nature of child welfare work. Preventive ideas had gained ground in the West, and were now being appreciated by ordinary people. This process had scarcely begun in India. Prevention was not applied, even by the educated to obvious diseases, such as plague, cholera, and smallpox, though its success had been amply demonstrated.

Up to now there were very few perfect child welfare schemes in India, and many people had been "put off" by the way in which the work had been undertaken. When one visited various welfare centres and one saw the mistakes that had been, and were still being made, one could not but acknowledge sadly that objections on this ground were too often valid.

In many places one saw the centre whose work should be preventive turned into a dispensary, and a very inferior one at that, or into a place where charity was doled out. No attempt was made to follow the history of infants by means of regular visiting, ante-natal work was not organized, nor was there any teaching of mothers. The work was carried on by those who were poorly trained, and with insufficient education to carry it on their own initiative.

In India, welfare work up to the present consisted chiefly of scattered bodies in various towns working independently of each other. The combination of "official"—that is, municipal and governmental—and voluntary societies was the commonest method of work, and on the whole was the best method under present circumstances in India. A voluntary committee was more elastic in its methods than an official one and had more of what, for want of a better word, was termed "soul." In such cases the "official" representatives on the committee exerted a steadying influence on the less experienced but more spirited "non-officials."

The relation of all these bodies to the existing public health authorities was somewhat loose, and tended to overlapping and a rivalry that was detrimental to the work as a whole. The Directors of Public Health were usually in sympathy, and sometimes lent active aid, but they had no legal power either to advise or control.

This was a serious weakness, and pointed to the need of an inspecting and supervising authority for each province, or at least for each larger province. What was lacking in India was the "third member" in the partnership between voluntary workers, local authorities, and the State. There might be excellent financial and other reasons why that was so, but it was a great weakness, and until it is remedied they could not build their child welfare work on a firm and lasting foundation.

Dr. Young advocated the provision of grants by provincial councils in the budget of the Directors of Public Health. She also advocated the appointment of a whole-time medical woman, with special experience of child welfare work and an aptitude for organization, working under the Director of Public Health.

They ought also to press for the improvement of the registration of births which was known to be defective. Training of *dais* was another point which merited their serious attention; they should be induced to attend classes

for instruction. If the municipality was progressive, it might be able to enforce the attendance of *dais*.

Among the accessory activities advocated by the lecturer were sewing or hygiene classes for mothers, the supply of milk or foods, and propaganda work. She deplored the lack of voluntary workers in India. Indian women were hindered from taking up the work by lack of education, lack of leisure, and by social customs which placed obstacles in the way.

Dr. Young referred to the necessity for providing training centres for women doctors. It was difficult to get the right type of character, apart from intellectual ability. Yet that was essential in this work. The placing of medical women in charge of maternity and child welfare schemes was an excellent move, but had one or two drawbacks. In the first place, the idea underlying it in the minds of the committee was often one of so-called economy. They thought it cheaper to have some one who could do both curative and preventive work. The effect on the work was disastrous.

Education of the people until they understand the advantages to the community of child welfare work was essential. Child welfare work must necessarily be a slow process, but it must take effect ultimately, and the educational work would, at the same time, sweep away the other existing difficulty of illiteracy.

Concluding, Dr. Young said she was convinced that the rise of the general level of education in India would achieve more for the progress of child welfare work than any other factor.

OBSTETRICS AND GYNAECOLOGY.

This Section was presided over by Dr. Kedar Nath Das, C.I.E., the distinguished Principal of the Carmichael Medical College. Dr. Margaret Balfour read an exceedingly interesting paper summarising the results of her two years' enquiry into the causes of death during pregnancy and labour in India.

Two hundred and forty-four deaths had occurred among a series of 11,343 cases analysed. The causes of death were as follows:

	Deaths	Per cent.
Anæmia of pregnancy	87	35.65
Puerperal sepsis	43	17.62
Eclampsia	25	10.24
Osteomalacia (its consequences) ..	22	9.01
Hæmorrhage	29	11.88
Other complications of pregnancy and labour	38	15.57

When these figures are compared with similar figures from other countries it appears in a general way that in India accidents and complications of labour are fewer, but the diseases of pregnancy are much more frequent.

(a) *Anæmia of pregnancy* resembles Addison's pernicious anæmia but differs from it in its more sudden onset, its more rapid course and its lack of remissions. It occurs in all parts of India.

The symptoms usually commence after the middle of pregnancy. Fever is often an initial symptom, followed by œdema, swelling, pallor, weakness. In 38 per cent. of a series of 150 cases diarrhœa occurred, in 40 per cent. vomiting, in 31 per cent. sore tongue, 29 per cent. were primipare. Death occurred in 42 per cent. of the cases, most often within 24 hours of delivery, but was sometimes delayed many weeks. 53 per cent. of infants were stillborn and another 15 per cent died a day or two after birth. None showed signs of anæmia.

In the blood picture the red cells were much reduced, the colour index was high. There was rarely leucopenia. Blood platelets were absent or scanty. Anisocytosis was always present, poikilocytosis usually so. Nucleated red cells were present in about half the cases. Post-mortem examinations were rarely possible but in two cases evidences of hæmolytic were found in the liver and spleen and aplastic areas were present in the bone-marrow.

(b) *Eclampsia*.—Its incidence varies both as to frequency and severity in different parts of the country.

(c) *Osteomalacia* occurs most frequently in the Northern and Central parts of India, less frequently in the West, and is absent from the South. It is believed to be due to a deficiency of Vitamin D. or lack of sunlight but this does not explain its unequal distribution in parts of India.

The influence of community.—In India speaking in a broad sense we have 3 communities of women living side by side, subject to the same climatic and housing conditions, equally exposed to endemic and epidemic diseases but differing as regards certain important particulars, namely, diet, literacy, domestic habits and customs relating to marriage and childbirth. These communities are the Hindu, Mahomedan and Christian. Particulars relating to the incidence among them of the chief diseases of pregnancy were obtained by means of a questionnaire sent out and are shown in the tables on p. 217.

It will be seen that both tables show the incidence of all three diseases to be greatest among Mahomedan women and least among women of "other" class who are very largely Christians. Some details follow showing the proportion these cases bear to the number of births in Bombay and the size of the different communities in India.

Facts regarding the different communities which might influence the incidence of the diseases of pregnancy are:—

- (1) Literacy.
- (2) Diet.
- (3) Early marriage.
- (4) Consanguineous marriages.
- (5) Domestic habits.

In conclusion the author pointed out that India should be an ideal country for obstetric research but workers are hampered by the difficulty of getting information from the records of most maternity hospitals. Records are kept in accordance with requirements of the Local Government for its annual report. All that the Government of Bombay requires is:—

1. The number of normal labour cases.
2. The number of abnormal labour cases.

Some Local Governments do not even require so much.

The numbers of different obstetric operations done have to be filled in, but not the causes which rendered them necessary. Hence these particulars are often not noted down on the hospital case-sheet and much valuable information is lost. The information contained in the Public Health Reports of large towns is also scanty although in some towns many of the deaths in childbirth are certified by medical practitioners. If Local Governments would require information as to the diseases of pregnancy from aided maternity hospitals and wards, and medical officers of health would enter anæmia of pregnancy and osteomalacia (as a contributory cause) under their death headings, much more light would be thrown on the conditions of childbirth in India.

Dr. Balfour's paper was followed by one by Dr. A. Emmanuelov and Dr. M. M. Mehta on the results of bacteriological investigation of the fæces and urine in cases of the anæmia of pregnancy, contrasted with normal controls. The principal pathogenic organisms isolated were the *Bacillus welchii* and streptococci, and their methods of identification and separation and their pathogenicity were discussed.

Dr. Agnes Scott then read a paper on osteomalacia in India. The disease shows a curious geographical distribution in this country. It is practically absent from the Madras Presidency; but very prevalent in Northern and Eastern India and in Kashmir. Hindus, and especially the *bania* and *kshatta* castes are affected in North India; in West India it chiefly affects Mahomedans. The chief predisposing causes are insanitary conditions, lack of sunlight and of exercise, whilst the disease is practically confined to women of the child-bearing period. The influence of child marriage, prolonged lactation, and the purdah system were discussed. Tetany is a common

APRIL, 1928.]

Incidence of osteomalacia, eclampsia and anæmia by community in Bombay Hospitals.

accompaniment. The general prevalence of the disease, as judged by the number of Cæsarean sections carried out for its results in 30 hospitals for women in North India was discussed, and an analysis presented of 73 cases of late rickets and osteomalacia observed at Delhi.

PROTOZOOLOGY, SPIROCHÆTAL INFECTIONS. TICK TYPHUS.

This Section met on Dec. 9th under the presidentship of Dr. Brug of Java. Lieut.-Col. R. Knowles read a paper on the influence of the thyroid gland on the course of a protozoal infection, viz. surra, due to *Trypanosoma evansi*. He showed that the control of the thyroid gland over resistance or susceptibility to such an infection was an indirect one; in animals fed on an intensive course of thyroid feeding an occasional animal might put up an amazing resistance; whereas in animals in which sub-total thyroidectomy had been previously carried out the disease assumed a hyper-virulent form. The trypanosomes apparently lived on the blood sugar; the content of this was controlled by the activity of the adrenals and the liver, and hence the thyroid control over the course of the disease was a partial and incomplete one.

The same author then read a paper by himself and his colleagues on the life-history of *Spirochæta anserina* in its vertebrate host, the fowl, and its invertebrate host, *Argas persicus*. The true life-cycle, as studied in fresh preparations under the dark-ground, appeared to differ from that described by Hindle and previous workers. In the fowl there was one attack only of fever, which either killed the bird, or at the crisis of which the spirochætes gathered into ever increasing tangles in the blood, became immobile and disintegrated. Tangle-formation in either host appeared to be the inevitable prelude to death of the spirochætes; there was no evidence of any intracellular phase of the parasite, and after the spirochætes had disappeared from the blood stream they could not be found in any internal organ, except—occasionally—in the brain. In the tick the course of the infection was relatively simple. The greater majority of the spirochætes gathered into ever increasing tangles in the

gut, became immobile, and disintegrated. The few survivors underwent a very rapid multiplication until there was finally produced a swarm of exceedingly minute and delicate forms—"tenue forms," as they might be termed, with a delicate terminal flagellum at each end. These now invaded the cœlomic cavity of the tick, and from it all the viscera of the tick, but especially the salivary glands, and in the female tick the coxal glands. Infection of the glands with the "tenue forms" was progressive, whilst the residual infection in the gut gradually died out, and the spirochætes in the salivary glands gradually grew up into the adult type of spirochæte and multiplied rapidly. Experimentally the tick became infective to the fowl at the 7th day—possibly earlier—and remained infective for some months at least.

Lieut.-Col. J. W. D. Megaw, C.I.E., I.M.S., then read a paper on a typhus-like fever which is probably conveyed by ticks. He brought forward evidence to show that this fever is widely and sporadically distributed in India. The disease is strictly sporadic and occurs in persons who have been living in jungle, and it does not spread from man to man, as does louse typhus. In several cases the onset followed within a few days after the bite of a tick, whilst in all other cases it was more likely that the disease was conveyed by a tick than by any other arthropod.

A similar disease had been reported from many other parts of the world, although the authors of the accounts concerned had sometimes wrongly regarded the disease as being dengue or paratyphoid fever. Animal inoculations had been singularly unsuccessful; the Weil-Felix reaction was usually negative, although in certain cases it was positive to certain strains of *Bacillus proteus* X 19, while negative to others. The probable reservoir of infection was a rodent of the wilds.

Dr. C. Strickland suggested that the possibility of transmission by a mite should be considered, as it had been shown that the virus of tsutsugamushi disease was transmitted by mites, in some cases without a local sore appearing. He also discussed the possibility of hares

and other wild animals serving as reservoirs of the disease. In reply Colonel Megaw agreed that arthropods other than ticks ought to be investigated, but held that all the evidence available pointed strongly in the direction of the tick. He emphasized the fact that tick bite had been proved to have occurred in several of the cases, and he believed that the other cases might well have been caused by the bite of ticks which had not been detected.

Dr. C. Strickland then read a paper on an epidemic of pseudo-typhus in Southern Queensland in 1925. It was popularly supposed that this epidemic had some connection with a mouse plague which was prevalent locally at the time; and he discussed in detail the applicability of the conclusions drawn from this epidemic to the sporadic typhus-like disease of India. A short discussion followed.

Dr. Otto Schöhl then read a paper on experimental frambæsia in the monkey, *Macacus rhesus*. This was illustrated by a series of magnificent lantern slides illustrating every phase of the experimental disease in the monkey, and its histo-pathology.

IMMUNOLOGY AND CHEMOTHERAPY.

This Section was presided over by Professor S. Hata, who, with Ehrlich, discovered salvarsan. He read a paper dealing with the factors influencing the therapeutic value of salvarsan solutions. At Professor Hata's suggestion, Professor Komatsu is carrying out an investigation at the Kitasato Institute on the changes in toxicity and in therapeutic value of salvarsan solutions when administered either simultaneously or admixed with other parasitocidal substances such as bismuth, mercury, and antimony. It has been found that the H-ion concentration of the solution has a marked effect on the therapeutic efficiency of neosalvarsan. The enquiry is at present continuing, and its results promise to be important.

Prof. Hata's paper was followed by a discussion. At the afternoon session the chief paper was one by Major R. B. Lloyd, I.M.S., on the clinical aspects of the Wassermann test.

"The object of this paper is to describe certain aspects of the clinical application of the Wassermann test as used in Bengal. With a reliable technique and adequate controls, the test is as valuable in the East as in the West. The first part of the paper refers to the positive reactions which have been reported in malaria. Some of the earlier reports were based on imperfect technical methods now discarded, and in certain instances the precautions taken to eliminate associated syphilis were clearly inadequate. Excluding certain papers which are defective in these two particulars, the weight of evidence is against malaria being responsible for a positive Wassermann reaction. The writer has specially examined this question, and finds no evidence that malaria causes a positive Wassermann reaction. This is a point of great importance as, were this so, the value of the Wassermann test in India would be in great measure discounted.

Secondly, yaws is a disease met with in India in which a positive Wassermann reaction is found as a regular phenomenon. This is a matter of no great practical importance as the lesions of yaws are characteristic.

The next part of the paper describes the work done during the last four years jointly by Dr. Muir of the Calcutta School of Tropical Medicine and the writer, who have investigated the causation of the positive Wassermann reaction in leprosy, chiefly from the point of view of the effect, clinical and serological, of anti-syphilitic treatment upon such cases. Earlier workers found a high proportion of Wassermann-positive cases in leprosy, and concluded that while syphilis is obviously accountable for certain of the positive fixations, yet there remains a considerable proportion not so due; and which they attributed to leprosy itself. We have examined the Wassermann reaction in the various types of leprosy, and have compared the percentage of positive reactions

obtained in a series of over a thousand definitely diagnosed cases with the syphilis rate of the Calcutta hospital population, which is estimated to be from 15 to 20 per cent. We find in the early or mild types of leprosy, both dermal and neural, that the Wassermann-positive percentage is within this figure; and of twenty-one cases of this class subjected to anti-syphilitic treatment, every one became Wassermann-negative; showing that all these reactions were due to associated syphilis. The case of the advanced dermal types of leprosy is more complex. Here 50 per cent. or more are found to give a positive Wassermann reaction. Of the Wassermann-positive cases in this class, three-fourths respond to anti-syphilitic treatment, the reaction becoming negative. The number of positive reactions met with in these advanced dermal types is found also to depend on the Wassermann technique employed. Kolmer finds with his new method, which has important technical differences from the methods ordinarily employed, that all positive reactions are due to associated syphilis. With what may be called "ordinary" modern techniques, there are, in addition to those due to syphilis, certain reactions which are falsely positive due to experimental factors. Our own results showing the effect of treatment indicate that a high proportion of positive reactions obtained by "ordinary" techniques in Bengal are due to associated syphilis, which is here present to an extent amounting to two to three times the syphilis rate. The most probable explanation of this is, we believe, that tissues damaged by the syphilitic virus probably form an excellent soil for the advance of the leprosy process; the result of which is that mild cases soon tend to pass into the graver forms of the disease, and therefore, the Wassermann-positive cases tend to accumulate in this category. Wassermann tests on leprosy cases are now a routine at the Calcutta School of Tropical Medicine; and in the event a positive reaction being obtained, anti-syphilitic treatment is given in the form of Avenyl, a new mercury compound, administered dissolved in hydnocarpus oil or esters. Apart altogether from the change in the Wassermann reaction, the clinical improvement in many cases of leprosy effected by this double treatment is very remarkable. Dr. Muir has found that Wassermann-positive leprosy cases are resistant to anti-leprotic treatment and a Wassermann-positive patient is never chosen when the effect of any drug is to be estimated.

The next part of the paper refers to the routine use of the Wassermann test in the examination of medical cases in the Calcutta Hospitals. As might be expected, many unsuspected cases of syphilis have been brought to light. Notes of some cases are given which were difficult of diagnosis clinically, and in which the Wassermann test was crucial; the correctness of the Wassermann finding being proved by the disappearance of the symptoms under anti-syphilitic treatment. A few notes are also given illustrating the part played by associated syphilis in preventing or delaying cure in other diseases, e.g., Wassermann-positive kala-azar cases tend to be resistant to specific antimony treatment, and operations for glaucoma may fail in a Wassermann-positive case.

In conclusion, the writer remarks that as the Wassermann reaction has attained its immense reputation by its concordance in an overwhelming proportion of cases with the clinical finding, it follows that the ultimate diagnosis of a case must be made by the clinician, who is always ready to appreciate the value of a test which, if properly performed, almost invariably gives a correct indication.

Major Chopra also read a paper by himself and Dr. S. Chaudhury on the physical properties of normal and pathological sera, of which the following is a summary:

The hydrogen-ion-concentration of sera has been determined by the hydro-quinhydrone method and their viscosity, gold number, conductivity and iso-electric point have been carefully worked out. There is a slight drift to pH to the alkaline side in the case of kala-azar sera. Viscosity of kala-azar serum is also a little increased, while no appreciable difference can be recognised

in the values of gold number and conductivity. The isoelectric point of kala-azar serum is definitely more alkaline than those of other sera. Incidentally, the precipitation produced by kala-azar sera with organic compounds of antimony can be explained on the basis of these physical constants. The coagulation value of these sera with $\text{Al}_2(\text{SO}_4)_3$ and FeCl_3 have also been determined. Gel formation with $\text{Al}_2(\text{SO}_4)_3$ has also been studied. It has been found that the concentrations of $\text{Al}_2(\text{SO}_4)_3$ at which leprosy and kala-azar sera form gels are distinctly different from those of the other sera. Explanation on the basis of the change of concentration of different proteins has been suggested. Experiments are being conducted to elucidate and correlate all these precipitations with electrolytes in the case of different sera.

Other papers in the Section were one by Dr. U. N. Brahmachari on the relationship between the antimonial compounds and their therapeutic properties, and by Major Labernadie on the carrying out of the Wassermann reaction without an incubator.

HELMINTHOLOGY.*

There were thirteen papers listed in this Section, but of these only seven were read; three were on filariasis, and the remaining four dealt with hookworm disease. Therefore, although the Section was somewhat limited in scope, the two most important helminthic infections affecting India were dealt with.

Colonel S. L. Brug of the Dutch East Indies Service, described what appears to be a new microfilaria found in the blood of human beings in several islands of the Dutch possessions in the East Indies. He based his opinion on its distinct morphological differences from *Microfilaria bancrofti*, and on the fact that as far as the investigation has been carried out the indications are that this microfilaria does not develop in *Culex fatigans*. He also pointed out that this discovery may be of importance in explaining the variation in the predominating symptoms of filariasis in different parts of the world.

The papers by Dr. Vishnu Korke on the findings in a filaria survey in the district of Gaya in Orissa, and by Dr. Sundar Rao, Calcutta, on the distribution, and manifestations of filarial infection in Calcutta are perhaps of more local than of general interest. The latter author showed that 10 per cent. of the population of Calcutta are infected, and that the infection is heavier in the more congested localities. Filarial fever is the commonest manifestation; the other lesions being elephantiasis, orchitis, chyluria, and abscess, whilst lymph-scrotum, lymph-adenitis and lymphatic varix are rare. *Culex fatigans* is the carrier in Calcutta.

Dr. Korke also contributed two papers on hookworm disease, as the result of an investigation at Gaya. In the first paper he showed that hookworm infection is heavier in the northern, more fertile, plains than in the hilly, more barren, portion of the district lying to the south, but there is more actual hookworm disease among the hill population than there is on the plains. This is explained as follows; the plains dwellers live under better conditions and are better fed than the hill dwellers; therefore the former can better resist a heavy infection than the latter. In his second paper he showed that the hæmoglobin index coincided with other evidence of the severity of hookworm disease.

Dr. J. F. Kendrick of the Rockefeller Foundation, who has been carrying out a hookworm survey in Madras Presidency for some years, gave a detailed account of this survey. He brought forward conclusive evidence that there is a close correlation between egg counts and the degree of anaemia, and by the fortunate circumstance of being able to observe over a long period undoubted pure infections with *Ancylostoma duodenale* and *Necator americanus* he was able to prove that the pathogenic effect of the former worm is relatively much greater than that of the latter.

An account of a hookworm survey in Ceylon was given by Dr. W. C. Sweet of the Rockefeller Foundation. By the application of the egg counting method it was possible to express the terms of infection for the whole island as one in which fifty per cent. of the population had hookworm disease, rather than the ninety per cent. who were infected. He also expressed the opinion that too much rain may be as detrimental to the development of hookworm larvæ as is too little rain. This is a point of considerable interest, and enquiry on this question in many parts of the world might produce valuable information.

OTHER SECTIONS.

Considerations of space preclude us from going into details with regard to the other sections. In the Section on *Surgery*, the chief subject was filariasis, with the surgical aspects of which Sir Frank Connor, I.M.S., dealt, and Major K. K. Chatterji with its surgical pathology. The latter author also dealt with the surgical aspects of chronic and latent amoebiasis, much on the lines of the useful chapter in his recently published book on surgery in the tropics.

In the Section on Dentistry Mr. H. A. Taylor, I.D.S., read a paper on oral sepsis, and Dr. R. Ahmed, D.S., one on the relationship of *pan*-chewing to pyorrhœa alveolaris in Indians. He made out a very strong case for the baneful effects of this habit, and implored that every effort should be made to eradicate it, and to preach its evils to the people of India.

In the Section on Ophthalmology Lieut.-Col. W. V. Coppinger, D.S.O., I.M.S. read a paper on glaucoma as seen at the Calcutta Eye Infirmary, 1926-27. Glaucoma, he concluded, is not merely due to obstruction to the drainage of the eye, but is associated with a condition of loss of pressure equilibrium in the eye. Colonel Coppinger gave some very interesting facts with regard to the incidence and characters of the glaucoma of epidemic dropsy. Glaucoma was also dealt with by Mr. S. K. Mukerjee, F.R.C.S. of Calcutta in an able and informative paper. A very striking paper, and one illustrated by a very fine series of coloured drawings was that by Major E. O'G. Kirwan, I.M.S. on the ocular complications of leprosy.

Of the Veterinary Section, we have unfortunately received no report; it was characterised by a miscellany of papers. In connection with the Scientific Exhibition a very fine series of exhibits was put up by the Imperial Veterinary Research Institute, Muktesar, by Mr. J. T. Edwards, F.R.C.V.S., and his colleagues. This was exhibited in the Pathology Department of the Medical College, and it is unfortunate that more people did not visit it, owing, largely, to the scantiness of direction posts, and being ignorant of its existence. The exhibit covered the whole range of the Institute's activities, and showed something of the very fine work being carried out at Muktesar.

In the Mental Hygiene Section Lieut.-Col. Berkeley-Hill, I.M.S. put in a strong plea for the study of the mental side of tropical diseases. The following is a brief summary of his paper. There is at present no mental side to tropical hygiene. Hitherto the subject of mental hygiene has met with little attention in tropical countries. Books on tropical diseases hardly mention mental disorders. There are two books which contain short references to mental disorder peculiar to tropical countries: Schaube's "*Krankheiten der Warmen Lander*" and Mense's "*Tropen Krankheiten*." In 1926, the Bishop of Singapore wrote to the *British Medical Journal* asking to be informed what is the cause of the upset of mental balance which is so common among Europeans in the tropics. To the Bishop's enquiry the *British Medical Journal* published eight replies from various doctors. The amazing diversity of opinion expressed in these letters only tends to show how ignorant we are about mental disorder, especially of the neuroses which beset Europeans resident in hot countries. Early in 1927 Lieut.-Col. H. W. Acton of the Calcutta School of Tropical Medicine, delivered before the Bengal Asiatic Society, a lecture entitled "Neurasthenia

* By Dr. P. A. Maplestone, D.S.O., Ankylostomiasis Research Worker, Calcutta School of Tropical Medicine.

in the Tropics." These examples practically constitute all that has been published about psychopathic disorder among Europeans in tropical countries. The principal mental disorder amongst Europeans in the tropics is probably an anxiety neurosis. The reasons for this: How the conditions of life of many Europeans in tropical countries favour the development of an anxiety neurosis. The treatment and prevention of anxiety neurosis. Other types of mental disorder. Tropical mental hygiene. What the French have done and are doing in the tropical colonies of France. What other European countries with interests in the tropics might do. What has been so far done in India. What might and should be done.

In the same Section Capt. J. E. Dhunjibhoy, I.M.S. read a paper on Indian hemp as a factor in the causation of insanity in India. The following were his conclusions.

Connection of Hemp Drugs with Crime.—Habitual use of hemp drugs degrades the mind and character of the consumer and predisposes him to crime in general. Thus the hemp is one of the most efficient means for increasing the criminal classes. It is also largely consumed by bad characters and badmashes to fortify themselves for crimes. Bhang is a very useful weapon in the hands of criminals for looting ornaments from prostitutes and children. Similarly, ganja generally mixed with dhatura and other potent drugs is a very useful weapon in the hands of criminal gangs to make an innocent man commit murder of another in order to suit their purpose. Unpremeditated crimes, especially murders or running amuck, are not uncommon occurrences with sudden large doses of hemp drugs.

Conclusion.—The Indian Mental Hospital at Ranchi has a male population of 1,200 and the history of indulgence in hemp drug could easily be traced in 30 to 40 per cent. of this population. On analysis of 1,200 cases it was found that in cases of 138 patients history of indulgence in hemp drugs was strongly corroborated by (1) Descriptive Roll which is usually filled up by police after due enquiry from the relatives and friends of the patients.

(2) Patients' own statements, and

(3) Peculiar eye condition mentioned above.

In other cases one or two of the above factors were absent.

"In conclusion I am strongly of opinion that insanity is the inevitable result of the use of hemp drugs, whether in excess or in moderation for a prolonged period, and that it is induced earlier in cases of neuropaths and psychopaths. I am also of opinion that the hemp drug is a direct cerebral poison and I put this drug without the slightest hesitation above alcohol, opium and cocaine in their injurious tendencies such as causation of insanity in India."

A number of valuable, but rather abstruse papers were presented at the Section of Medical Entomology. Major J. A. Sinton, V.C., I.M.S. dealt with the classification and identification of members of the genus *Phlebotomus*, and Assistant Surgeon R. O. A. Smith, I.M.D. with their breeding in nature and in the laboratory. Two papers of very great interest, illustrated by very fine microscopic preparations and lantern slides, were those by Mr. M. O. T. Iyengar of the Bengal Public Health Department on the protozoal and nematode parasites of *Anopheles* larvae. The same author also contribute a very well drafted paper on the regional distribution of anophelines in Bengal; he divided the country into montane, sub-montane, upper deltaic, lower deltaic, and coastal zones and showed how the distribution of the 26 different species concerned varies according to the tract of country concerned. Mr Iyengar's four contributions to the Congress were all of them of a very high order of merit, admirably illustrated, and show the splendid and well-organised work which is being done by his department.

In the Section on Bacteriology Dr. C. McGuire, Dr. G. O. Panja, and Dr. K. Bannerjee, all of Colonel

Acton's department at the Calcutta School of Tropical Medicine contributed a series of papers of merit dealing with the commoner tropical skin diseases and the streptococci of the tropics. These covered much the same ground as previous papers in this journal, and need not be discussed in detail; they show how rapidly tropical dermatology is becoming a science, and not a hotch-potch.

It is quite impossible within the limits of this review to give any full account of the tremendous scientific interest of the Congress. In practically every Section the meetings were not merely well attended, but crowded. From the scientific and professional point of view, we believe that the Seventh Congress will be a most memorable one in the history of the Association.

CONCLUDING GENERAL SESSION.

The concluding general session of the Congress was held on Saturday morning, the 10th December, in the Senate Hall of the Calcutta University, with Major-General T. H. Symons, I.M.S., presiding. The Hon. Sir Mohammad Habibulla, Member of the Viceroy's Executive Council, addressed the meeting on India's position in international public health and the medical research work in progress in India. The following is an abstract of his speech from the *Statesman* of the following day.

He said: "I must in the first place, express my regret that I was unable to be present at the inaugural meeting of the Congress, avail myself of my presence in your midst to-day to echo the sentiments expressed in the message of His Excellency the Viceroy, which was conveyed to you by His Excellency Sir Stanley Jackson, and to express the hope that your stay in the second city of the British Empire has been interesting and agreeable.

"That it has been strenuous, I can easily infer from your programme, of which I have seen a copy, and from the summary of your transactions which your energetic Secretary handed to me. To those of you who propose to visit other centres of medical and scientific research in India, I wish a pleasant and instructive tour; to those who must return from Calcutta to their official homes, I wish God-speed. To all of you, whether delegates from abroad or from the various parts of India, I express the thanks of the Government of India for the contribution which you have made by your meetings and discussions to the promotion of medical science, and of friendly understanding between men engaged on a common beneficent task.

"I utter no mere empty platitude of politeness when I say that I have followed your activities with the keenest interest. Though a layman, it is my proud privilege to-day to be in charge of the medical and public health Portfolio of the Government of India. That imposes on me an official obligation to follow, as best I can, the endeavour and achievement of men engaged in the fields of medical administration and research.

But there is also a personal side to my interest. Throughout the active portion of my life, I have been intimately concerned with the administration of medical relief and sanitation. First, as the civic head of the town of my adoption in the Madras Presidency, then as the principal civic executive of the metropolis of that Presidency, and subsequently in succession as a member of the Provincial and Imperial Governments, I have had to concern myself with measures designed to combat disease and alleviate human suffering. This long experience and association have made administration of the subject which is your life's work more than just, a dry duty to me.

"I shall not presume to assess the technical value of the work which you have accomplished during your present session in Calcutta. The list of the questions which you have discussed is long; their scientific aspect to a non-scientist like me an esoteric mystery; their analysis or appraisal a task beyond my competence. But after glancing through the summary of your proceedings

and listening to your resolutions, I find that grim diseases, such as plague, cholera, malaria and kala-azar, which from time to time ravage this country, have been claiming your attention.

"I am confident that the light which investigators from abroad attending this Congress have shed on the problems connected with these forms of human affliction, will prove of the utmost value to our own workers. I also trust that an account of our methods, and first-hand experience, however slight, of the procedure, technique and scope of our inquiries in the domain of tropical diseases, will prove of some help to them. For we have, alas! only too many opportunities and ample material for work in this field and I may, in all modesty, but with due regard to their achievement, claim that by our pioneers in medical research, the opportunity has been well and widely used to the benefit of humanity, and the advancement of science.

"The names of Ross, Rogers and Cragg—I must spare those present here to-day the blushes which are the physical reaction of true workers to praise—are not only worthy of my tribute, but are guarantees of the claim which I have made on behalf of the noble band of the servants of medical science in India.

"Nor must I omit mention of that great Indian, whose researches in the field of plant life have opened up fresh and limitless avenues of speculation, of inquiry and of practical achievement to doctors, no less than to biologists. For is not the problem confronting both, one of solving the mystery by which the creative energy that we comprehensively designate life suddenly or slowly freezes into the inertness that is called death? The door leading to such solution may be remote and the master-key yet undiscovered. But I may state with some degree of confidence that among the torch-bearers who have helped to illumine the path, the name of Sir Jagadish Bose will rank high.

"I have spoken so far on the aspect of your work which belongs to the development and diffusion of scientific knowledge. I shall now speak of another aspect of equal importance—the promotion of friendly intercourse between scientific men. To my mind, that is as much as a necessity of the future as its beginning is one of the auspicious and distinctive features of our 20th century civilization. To the Far Eastern Association of Tropical Medicine belongs the credit of first making such intercourse a reality.

"The League of Nations, to whose initiative in the sphere of international co-operation the world owes so much and the Rockefeller Foundation whose truly catholic generosity has rendered immense service to the progress of medical science, have stimulated and accelerated its beneficent development. We in India are willing and ready to play our part in the scheme of co-operation by intercourse. That was one of the motives which led the Government of India to decide to invite the Association to hold its Seventh Session on Indian soil. In the very near future, we hope to hold an interchange of health officers under the auspices of the League in this country.

"Next year we trust the League may find it possible to send their Commission of malarial experts to India.

"I need not remind the Congress that we have been participants in past gatherings of the Far Eastern Association of Tropical Medicine. It must also be known that India is a member of the International Health Office in Paris, and that at present her Public Health Commissioner has a seat on the Health Committee of the League of Nations, and on the Advisory Council of the Bureau of Epidemiology at Singapore. These are a few concrete instances of our desire for co-operation by association and intercourse. If more opportunities for co-operation arise, I am sure India will not be slow to respond to the call of service.

"But I have another motive in dwelling on our readiness for intercourse. There is an impression in some quarters that as a country where certain diseases are endemic, we are doing little to combat them, or to ensure that infection does not spread from our shores to other lands. You have been in Calcutta during an

epidemic of cholera which, for the time of the year, was considered by our experts to be serious. Some of you may have seen what is being done to cope with the outbreak. The fact that it has been rapidly brought under control is proof of the efficiency of the health organisation of this great city. Lt.-Col. Russell, who comes from my old Presidency, has given you some idea of what is being done in Madras. Those of you who undertake any of the tours that have been arranged will get an idea of corresponding activities in other parts of the country.

"I speak of these things not in any spirit of boasting, but to support the claim which I now propose to put forward, that in India we have nothing to hide. It is not suggested that the limit of what is desirable or possible has been reached. In a country greater in size than the whole of Europe without Russia and with a population of over 300,000,000, even a small measure of progress represents endeavour which would be equal to the achievement of perfection elsewhere. I confess that a great deal remains to be done and we need all the light and inspiration that the example of other countries can give us. But we plead not guilty to any suggestion that endeavour has not been quickened by the presence of danger or the breath of science.

"I do not wish you to disperse to-day with the impression that complacent egotism is the keynote of our attitude towards the problems which disease and the effort to prevent and fight disease present. As I have already said, we seek light and inspiration from every quarter. Recently, the Government of India have decided to appoint a committee to inquire into the working of their existing organisation of research and to make recommendations with a view to the establishment of a central institute with whose aid schemes of investigation now in progress in different parts of the country may be co-ordinated, and fresh avenues of inquiry explored.

"Your distinguished colleague, Sir Walter Fletcher, has kindly agreed to preside over the committee. Col. James of the British Ministry of Health who was once with us in India and who has since his retirement from the Indian Medical Service won fresh laurels in other fields, has also, I am glad to say, found it possible to agree to serve on the committee which will include two distinguished workers with recent Indian experience, viz., Dr. Row and Col. Christophers, F. R. S. The Government of India trust that their labours may impart to medical research in India fresh impetus and definiteness of direction.

"I must not detain you too long. You have worked hard and still have a busy round of engagements to go through. It would be inconsiderate of me to weary you with my discourse. I shall offer one word of explanation for the prominence which I have given to research in my remarks. It is because I feel that in the field of medical research, international co-operation can, at this stage, be most fruitful. And gatherings like the Congress provide the right opportunity and atmosphere for exchange of ideas and comparison of methods, for analysis of data and for synthesis of experience.

"Personal relations are established, personal affinities discovered, and misunderstandings of method and objective dispelled. Men separate with greater clarity of vision and strength of purpose to renew their tasks. May the 7th Congress of your Association conclude its labours in the consciousness of much good accomplished and with faith renewed."

On behalf of the foreign delegates Professor Shiga (Japan), Dr. A. L. Hoops (Straits Settlement) and Major Hitchens (U. S. A., and Philippine Islands) thanked the Government of India, the Provincial Governments, the Organizing Committee and others for the success of the Congress.

The following resolutions regarding the control and prevention of malaria, passed by the Malaria Section of the Congress, was confirmed by the meeting.

The Malaria Section of the 7th Congress of the Far Eastern Association of Tropical Medicine are aware of many instances of a great increase in the incidence of

malaria caused by the facilities given to mosquito reproduction by engineering works, either during construction or afterwards due to the different conditions brought about. This Congress is of the opinion that plans for railways, canals, harbours and all similar engineering works likely to affect the conditions producing malaria should be submitted to the proper Public Health Authorities and their Sanitary Engineers before being sanctioned by Governments.

As it has been represented that differences of opinion regarding the best method of controlling malaria sometimes cause doubt in the public mind and so may hamper the progress of anti-malaria work, this Congress takes the present opportunity to emphasize the fact that there is no single method of malaria control applicable to all conditions and all countries.

Nevertheless they consider that for towns, mines, plantations, large public works and similar aggregations of people, the control of the breeding places of the malaria-carrying species of mosquito is a method which should be employed, whatever other anti-malarial measures are put into force. Whenever possible this control should be effected by permanent works which eliminate entirely the sources of mosquito breeding.

For wide rural areas, specially those with scanty, poverty-stricken populations, the first step in the control of malaria is adequate research so that the conditions present may be ascertained and the best methods of control under the particular circumstances ascertained as a result of such research. Methods of prevention may here be of great variety and include drainage, flooding, jungle-clearing, the promotion of agriculture, improvement of housing and the general economic condition, education, etc., of the people. The systematic killing of infected adult mosquitoes, screening, the use of anti-malarial drugs, and a host of special methods have each also to be considered in their proper application.

The Congress desires to stress the need not only of thoroughly trained malaria research officers but of expert malarial engineers in whichever type of malaria prevention is at stake.

The meeting also decided that the Congress should be held triennially instead of biennially.

THE CONGRESS DINNER AT BELVEDERE.

The final function of the week was the Congress dinner at Belvedere, which had been very kindly lent by His Excellency the Viceroy. Over 500 members and guests were present, and we understand that this was the biggest public dinner ever held in Calcutta. The catering was in the hands of Frederico Peliti, and was admirably carried out; whilst the assembly was so large that the dinner was held in the ballroom at Belvedere, the tables covering the entire floor of the ballroom and also the recesses and verandahs. Loud speakers had been installed in different parts of the ballroom, so that the speeches were for the most part clearly audible. Ladies were present, including Her Excellency Lady Jackson, and the scene was a very brilliant one, the mess kit of I. M. S. officers—both new and old styles—and those of foreign delegates from the U. S. Army Medical Corps, of the Portuguese Medical Army Corps, and the French Army Medical Corps—lending colour values to the general scheme. Possibly the pheasant—which had been brought out in cold storage from England or Scotland—was a trifle tasteless, as is so often the case, but the dinner was a great success. We take the liberty of "lifting" the following account of the speeches from the *Englishman* of the 12th Dec. 1927.

In proposing the toast of the "Far Eastern Association of Tropical Medicine," His Excellency the Governor of Bengal said:—

"It is a great pleasure and privilege to propose for your acceptance the toast of the Far Eastern Association of Tropical Medicine. We in India have every reason to give a sincere response to such a toast as this, as there is no country in the world which has more cause to be thankful to scientists for services she has

received in the past, or more cause for hope for further assistance from them which she urgently requires in the future. She has reason to be particularly grateful to many who have assembled here this last week during the meeting of the Congress. There is scarcely any tropical disease known to man, to obtaining control of which they have devoted their professional skill, which does not afflict the people of India. In many countries in the East they have laboured towards the elimination of these scourges with remarkable success, and during the Congress they have willingly and generously given of their fund of knowledge for the benefit of those, who like themselves, are labouring to similar purposes in this country.

The benefits to be derived from the results of such a Congress, when properly applied must be invaluable. I can think of no work more estimable or which in itself should give cause for greater satisfaction than that which aims at the relief of human suffering from tropical diseases.

It has been demonstrated by results obtained in several Eastern countries that it is possible to control and even eliminate some of the worst scourges. It must be to your eternal credit that the only recompense you desire and receive is the gratitude of humanity.

I am glad to hear that your Congress has been a splendid success. This has been due to a large extent to the excellent organisation for which Colonel Cunningham and Colonel Stewart have been responsible, and they will be the first to agree also to the loyal co-operation of every one who attended the Congress.

In welcoming you to Calcutta, I expressed the hope that you would be able to give us useful advice in connection with our grave problems of disease. I understand that my hopes were amply justified and that our medical men have received much help, stimulation and encouragement. We trust that our guests and you may derive satisfaction by knowing that hundreds of medical workers from all parts of India have derived great benefit from the knowledge which has been provided for them.

Every member of the Congress will doubtless become a messenger, who will convey to many others the information which he has acquired, and in this way the efficiency of the whole medical profession of India will be greatly improved.

I understand there has been some difference of opinion with regard to some of the subjects which have been discussed. This is probably as well, as too great an agreement might create a feeling that further research was unnecessary.

On the other hand it is satisfactory to know that there has been a remarkable degree of unanimity as to the practical measures which are necessary to cope with such diseases as malaria, cholera, plague and kala-azar. While you all agree that more knowledge must be acquired, you also agree that more use must be made of the knowledge which at present exists.

Governments and local bodies will now have confidence in pushing forward measures which have received the approval of distinguished experts from every part of the world.

We in Bengal are glad to learn that the great campaign of inoculation against cholera, which is in progress, is regarded as one of the most effective methods of controlling the disease. It is not the only measure, but when we are attacking an enemy like cholera, we cannot afford to neglect any weapon, which has been proved to be effective.

The problem of kala-azar has been fully and ably discussed at your Congress and I am told that there is a general agreement that the line of research which was opened out by workers at the Calcutta School of Tropical Medicine and the Kala-Azar Commission is regarded as being full of hope. The methods of treatment are already so satisfactory that minor improvements are all that can be looked for.

I was interested to hear that the food supply of the people of India had received very special attention at the Congress. This subject makes a special appeal to

laymen, who not infrequently conduct dietetic experiments on themselves, though perhaps these are not always scientific.

I understand that you have spent some time in considering the ravages of the ubiquitous and iniquitous mosquitoes—those malevolent messengers of malaria. Your unanimous decision on their activities and how to meet them must prove a most acceptable guide to the Health Departments of our Governments. I am hopeful that you will yet teach the mosquito, when it takes its evening meal from me, that the mark of its gratitude it leaves behind would be more acceptable if less pronounced.

In proposing this toast I must not forget the ladies who have accompanied the Congress and who have graced our proceedings and honoured Calcutta by their presence. Their interest and assistance is a great stimulant to those who devote their lives to research in tropical diseases.

I have to couple with great pleasure this toast with the names of Dr. Heiser of the U. S. A. and Dr. Deggeller of Java. Dr. Heiser, as you are aware is a representative of the Rockefeller Foundation in the East and is one of the original members of your Association. Dr. Deggeller of Java is the General Secretary and Treasurer of the Association.

The value of this Congress which you have just completed is unquestionable and with all sincerity and with all gratitude from India I ask you to rise and honour the toast of the Congress of Far Eastern Association of Tropical Medicine."

THE CONGRESS EXHIBITION.

The Congress Exhibition was probably the most interesting one ever held in India. It consisted of two sections; (a) the main scientific exhibition; and (b) the commercial section. The former was unfortunately scattered over several buildings, owing to the diverse nature of the buildings concerned, such as the Calcutta School of Tropical Medicine, the Carmichael Hospital for Tropical Diseases, the Pathological, Anatomical, and Chemical Examiner's departments of the Medical College, Calcutta, and the new Eye Hospital, Calcutta. There were numerous sign posts about, but we believe that but few of the visitors recognised the completeness of the exhibition or studied it as a whole.

Many of the exhibits in the scientific section were of very great interest. Among these we may especially mention the plague exhibit by the Haffkine Laboratory, Bombay; this dealt in detail with the ancient and modern history of plague and antip plague work, and contained many old prints and illustrations. The rabies exhibit by Lieut.-Col. J. Morrison, I.M.S. and Capt. E. C. R. Fox, I.M.D. was of exceptional interest in its graphs of the results of treatment at the different Pasteur institutes of India, and its collection of photographs of unique cases. Colonel Acton's laboratory was transformed into a veritable picture gallery of the commoner and more important tropical skin diseases. Public health work was dealt with in Colonel Stewart's laboratory, including an interesting exhibit of the activated sludge process. Perhaps the finest exhibit of the whole lot was Major Shortt's wonderful exhibit on behalf of the Kala-Azar Commission; this showed an absolutely unique series of splendid microphotographs of the developmental cycle of *Leishmania donovani* in the sandfly *Phlebotomus argentipes*, with an equally fine series of microphotographs of the newly discovered gregarine parasite of *P. argentipes*, *Monocystis mackie*. In the same room the models by Dr. Young of Peking, illustrating the methods of caging an infected and an exposed hamster in a twin cage in order to investigate the rôle of the different biting insects in the transmission of kala-azar was the subject of great interest; as also his extremely ingenious apparatus for artificially feeding sandflies with cultures of *Leishmania* by a capillary pipette apparatus.

In all, the number of exhibitors (counting the Calcutta School of Tropical Medicine as unity) numbered

no less than thirty-one, and the exhibition remained open throughout the week. Lieut.-Col. R. B. S. Sewell, I.M.S. from the Zoological Survey had a splendid exhibit of the poisonous and non-poisonous snakes of India. Dr. Muir dealt fully with leprosy in its every phase. Lieut.-Col. R. Knowles' laboratory was full of protozoal and spirochaetal colour plates. Major Chopra had a very interesting and extensive exhibit of the indigenous drugs and herbal plants of India; Major Boyd one of the commonest poisons used in India. Colonel Megaw exhibited museum microscopes, and colour plates in connection with tick typhus, and charts of the geographical incidence of epidemic dropsy. A particularly fine exhibit was one by Major H. H. King of the Guindy Institute on filariasis in lizards, showing the phases of infection in the vertebrate and mosquito hosts, illustrated by wonderful specimens and microphotographs. The Central Research Institute at Kasauli had almost a room to itself, and put up a very fine show, chiefly illustrating malaria in India, and the activities of the Institute in the preparation of T. A. B. and other vaccines. The Indian Red Cross Society had a verandah to itself, and had a very fine collection of lantern slides, propaganda posters, literature, etc.

The special filariasis exhibit by Sir Frank Connor, Colonel Acton, and Dr. Sundar Rao occupied a room to itself, and was a museum of information. Colonel Cunningham's relapsing fever exhibit was of very great merit, especially his wonderful dark ground microphotographs. The radiological exhibit by Capt. Barnard of Madras was a very exceptionally fine one, including a magnificent series of cranial skiagrams taken in conjunction with his enquiry with Lieut.-Col. R. E. Wright, I.M.S. into the causation of optic neuritis and its association with diseases of the accessory sinuses and lesions at the base of the brain. Capt. Barnard has often exhibited at the annual meeting of the Radiological Society in London, and his work in India stands out as pre-eminent.

Colonel McCarrison's exhibits covered a very wide field, illustrating diseases due to dietary deficiencies, goitre, beriberi, and the effects of manganese salts on growth. In the new Eye Hospital, which we fear but few visitors penetrated to, Colonel Coppinger had a simply magnificent series of specimens and coloured plates of ocular diseases and injuries of all types. The veterinary exhibit, which we have previously alluded to, was one of exceptional merit.

The scientific side of the Exhibition, in brief, was so extensive, so well put together, that it might well have taken any member or visitor his whole week in Calcutta to go through it thoroughly. As it is, we fear that most of the members obtained but a partial idea of the vastness of the treasures exhibited.

The commercial section of the Exhibition, we understand, was an extremely successful one. It was held in the Anatomy Department of the Medical College, and the exhibits of new microscopes and microscopical accessories was truly wonderful. Most of the firms which advertise in this journal were represented.

SOCIAL AMENITIES AND OTHER INTERESTS.

The programme for the week was by no means confined to the sectional and general sessions, for every afternoon and evening saw social and other functions connected with the Congress.

On Monday evening, Dec. 5th, H. E. the Governor of Bengal and Lady Jackson held a reception at Government House. This was held in the ballroom, and nearly 1,000 guests were present. Many—perhaps the majority—were in mess kit, and the scene was a very brilliant one. On Tuesday evening Sir Jagadish Chandra Bose, F.R.S. gave a most interesting account of his researches into the mechanism of plant life, plant vitality, and the "heart" of plants at the Bose Institute in Lower Circular Road. This was attended by a very large number of the delegates to the Congress. The action of alkaloids on plant vitality was especially dealt with, and the use of the "resonant recorder" explained.

On Wednesday afternoon the Asiatic Society of Bengal was "At Home" to the foreign and official delegates, and the wonderful and historic collection of treasures which the Society owns, together with its unique historical collection of pictures by Rubens, Raphael, Burne-Jones, and others, was on exhibition. In the evening the Indian Museum was at home. The galleries had all been especially lighted with electric light, and this very famous and wonderful collection can never have been previously viewed to better advantage.

On Wednesday afternoon and Sunday morning special medical films were shown to members of the Congress by Madan's Theatres, Ltd. These comprised extremely interesting cinema records. They dealt with anti-plague measures in Java; with sleeping sickness in Africa; with antenatal and maternity work in India; and with general public health work in this country. A specially interesting film shown was one describing in full the wonderful organisation against cholera in connection with the Kumbh Mela fair in 1927 in the United Provinces. This is a celebrated five-yearly pilgrimage; the risks of cholera are very serious; and the measures taken, which were inspected in 1927 by H. E. the Viceroy, were extremely successful. Another film of special interest shown was one of the cultivation of living tissue by the Carrel method.

The "At Home" of the Calcutta School of Tropical Medicine was held on Monday afternoon, Dec. 5th, and the School was crowded from 4-30 to 7-30, the laboratories all being on exhibition. This ceremony constituted the official opening of the scientific side of the Congress Exhibition, most of which was housed in the School. Another feature of the week was the Garden Party at Government House on the afternoon of Friday, Dec. 9th.

CONCLUSION.

It is quite impossible for any one single reviewer to try and give a full, detailed, and connected narrative of the Congress, though we have attempted to do what we can. The official *Proceedings* of the Congress will probably not be published for another 18 months or so, and even then will only be available to full members, and will not have the world-wide circulation which we should desire.

There can be no question of the great success and international importance of the Congress, or of the dominant position which workers in India, both Indian and European, took in it. Since the Congress terminated there has appeared an attack upon it in the editorial columns of the January 1928 number of our contemporary, the *Calcutta Medical Journal*. We could afford to ignore this, were it not for the fact that the writer emphasizes the supposed fact that the utmost was made of the "very insignificant" part which the Indian Medical Service has played and is playing in medical research work in India, and the grossly official character of the Congress proceedings. The reply to the first charge, we hope, is evident to anyone who was present at the Congress itself. The reply to the second is that an official organisation of some sort is absolutely essential for a huge international Congress of this type, unless the proceedings are to be allowed to degenerate into the proceedings of a bear garden; adherence to a strict time table and very full organisation beforehand are necessary. The writer of this criticism singles out four distinguished Indian scientific workers whose work was "ignored" by the Congress. In doing so, he is singularly unfortunate. The first and second, Sir Jagadish Chandra Bose, F.R.S. and Professor Raman, F.R.S. are not medical men, and therefore could not attend the Congress; on the other hand both gave special evening demonstrations by special invitation to the members and delegates of the very important scientific research work upon which they are engaged. The other two distinguished Indian research workers who are mentioned are Rai Bahadur U. N. Brahmachari and Hon. Lieut.-Col. R. Row, O.B.E.,

I.M.S. Both were distinguished members of the Congress, and both read papers at it.

Our guests at the Congress were guests of the Government of India, and in general of the medical profession in this country. We trust that we have shown them everything fully, that we have kept nothing concealed up our sleeve, that we have done our best both in their interests and in ours. If the Indian Medical Service is in the effete organisation which the writer in the *Calcutta Medical Journal* believes it to be, doubtless we shall learn so from our foreign visitors; the speeches at the Belvedere dinner by the American and other foreign delegates at least do not lead us to believe this to be the case. On the contrary, we believe the Congress to have been truly international, of international importance, and that the work of both Indian and European research workers in India was well represented in it. There is nothing to be gained by misrepresenting the facts. We have no desire at all to enter into controversy; the function of this journal is to reflect the present state and activities of the whole medical profession in India of all classes, status, and creeds. We can but leave it to the future to decide whether India—as a whole—came out well or badly at the Seventh International Congress of the Far Eastern Association of Tropical Medicine.

Current Topics.

Government of Burma (Ministry of Education) Public Health Department.

Resolution; Indigenous System of Medicine.

Extract from the Proceedings of the Government of Burma, Public Health Department, No. 14S28, dated the 14th January, 1928.

THE Local Government has for some time had under consideration the problem of the regulation and improvement of the practice of indigenous methods of medicine in Burma. Proposals with this end in view have been made by the practitioners themselves, and the fear has occasionally been expressed that genuine doctors of the Burmese School are dying out and are being replaced by quacks and persons with the most meagre qualifications or merely the knowledge of a few words of Pali. It is hardly necessary to emphasise the danger of medical practice in rural parts falling into the hands of men who have neither western training nor such skill as a long apprenticeship under a recognized *sesaya* implies. But any attempt to abolish the quack without supplying the medical needs of the people in other ways seems likely to fail. It will be many years before medical training institutions in Burma can place modern scientific treatment within the reach of every villager. The great majority of the people are said to prefer Burmese systems of medicine, and the Hon'ble Minister believes that the problem of extending medical aid demands consideration, whether indigenous methods and practice can be so improved and regulated as to afford some medical relief to people who would otherwise obtain no relief of any kind. For some years courses of training in the rudiments of a sepsis and diagnosis have been provided for a limited number of *sesayas* in the hospitals at Mandalay and Bassein. The scheme, limited though it has necessarily been, has met with some success, and the *sesayas* themselves have been keen to learn. The Hon'ble Minister believes that the time has now come for an examination of the problems connected with indigenous medicine and has accordingly decided to appoint a Committee to consider and report on Burmese medicine and the best means of improving and encouraging it, should improvement be found feasible and encouragement advisable.

2. The Committee will be composed as follows:—
 - (1) Lieutenant-Colonel U. Ba Ket, I.M.S., Chairman.
 - (2) Dr. U. Maung Glay, Myochit Dispensary, Yegyaw.
 - (3) Taungtha Saya Hla, Thaton.
 - (4) Saya U. Kywe, Upper Pazundaung (opposite U. Nyo's place).
 - (5) Saya Maung Maung Lat, No. D. 1, Shan Road.
 - (6) Dr. U. Thein Maung.
 - (7) Dr. U. Tha Noo, K.S.M., A.T.M.
 - (8) Saya Nyo, Hinthapadawin, Mandalay.
 - (9) Saya Saing, Upper Oliphant Street, Rangoon.
 - (10) Saya Thin, Municipal Councillor, Ponnazu, Mandalay.
 - (11) U. Shwe Ge, L.M.&S. (Cal.), Hygiene Publicity Office Secretary.

3. The terms of reference will be as follows:—

- (a) To examine and report on Burmese systems of medicine.
- (b) To consider whether Burmese systems of medicine can be improved, and if so in what way.
- (c) To consider whether the training of *sesayas* should be undertaken by Government or left to private agency.
- (d) If training by Government agency is recommended to consider:—
 - (1) Whether training should be given in Government hospitals or in a separate institution.
 - (2) Whether training should be confined to young men fresh from school, or to practising *sesayas* or should be given to both.
 - (3) What teaching staff would be required.
 - (4) Detailed proposals regarding the length and nature of the courses, numbers of students, and the conditions to be laid down as to educational qualifications, stipends, etc.
 - (5) How textbooks in Burmese could be provided for the use of students.
 - (6) Whether a license should be granted to successful students.
 - (7) Whether Government should prohibit unlicensed practice and if so, after what period.
- (e) To consider what provision should be made for research into Burmese medicine.

Radium Treatment of Cancer of the Cervix.

By Dr. HELEN CHAMBERS.

Lancet, December 31st, 1927.

THE author reports that there is as yet no general agreement as to the best means of treating cancer of the cervix with radium. Many different methods are in use and they vary in the quantity of radium used, the dosage, and the method of distribution.

The success of radium treatment in cancer of the cervix depends upon the fact that for many months the disease is a local one. It involves a region which is accessible, and one to which a heavy dose of radiation can be safely applied if special precautions are taken.

The most serious objection to radium therapy is that it fails to treat pelvic lymphatic glands. They are only involved, however, in about 37 per cent. of these cases at the time of death, and as the majority of patients are first seen a year or 18 months earlier, it is reasonable to suppose that the greater number of patients when first seen have no gland involvement at all. This is supported by the fact that many cases are alive and well ten years after radium treatment.

It is essential to use multiple sources of radiation at the site of the growth, and Dr. Chambers describes a method by which the whole of the tissues involved can be acted on by the applications.

A similar method has been used in Japan (Ikeda) since 1914; the results are some of the best on record. This method has only been used in England since 1925 at two London clinics, and it is not in use at the present time anywhere else in that country. The

largest number of cases treated by this method and recorded in British literature have been treated under the auspices of the Cancer Research Committee of the London Association of the Medical Women's Federation. They report 117 cases with no death directly due to the treatment. Fifty per cent. of their cases treated more than a year ago are stated to be free from signs and symptoms of cancer; the percentage operability of these cases was not more than 15 per cent. These results are too recent to justify conclusions as to the ultimate value of the method, but as far as they go they agree with the foreign reports and compare very favourably with the results at those clinics which report 70 per cent. of cases as having died within a year of the patients first being seen. Hospitals are entirely without the facilities for providing it. With extended knowledge it is to be hoped that this state of affairs will very soon be rectified.

An Operation for the Alleviation of Deafness.

By VINCENT NESFIELD, F.R.C.S. (Eng.),
MAJOR, I.M.S. (Retired);

Ophthalmic Surgeon, Queen's Hospital
for Children.

Lancet, December 24th, 1927, p. 1338.

THE following abstract from the *Lancet* of December 24th, 1927, will interest our readers.

"In 1919, while serving in the Indian Medical Service and acting as surgical specialist of the Mhow Division, I was approached by many people suffering from deafness, and was unable to help them.

One day I found in the cantonment hospital in Jubbulpore a fine old Sikh of 65 or more lying on the operating-table; he refused to move until I had operated on him, as this was his lucky day. About a month previously I had extracted both his cataracts, and he could see perfectly, so he believed that the cure of his deafness was an easy matter. I had many times refused to operate, explaining that the eye was on the surface, and the organ of hearing hidden at the bottom of a long narrow canal embedded in the skull. It was these discussions that finally suggested to my mind the operation here described.

He was very importunate and had indeed taken an oath of starvation unless I operated, and so I asked the assistant to give him chloroform and operated on both ears. The man made an excellent recovery, and went home both seeing and hearing. This brought me such a stream of similar sufferers that I did not know how to cope with them.

The fundamental idea of the operation is simple. When deafness is due to obstruction of the Eustachian tube the treatment is to make a new passage leading from the exterior into the cavity of the middle ear behind the ear-drum.

The Operation.

The skin behind the ear is painted with tincture of iodine and a light general anæsthetic given, preferably chloroform, which ensures less bleeding. $\frac{1}{2}$ per cent. phenolaine (a local anæsthetic) is injected subcutaneously, and an incision is made close behind the pinna. When the periosteum is reached phenolaine is injected under it and also between the cartilaginous canal and the bony meatus. The periosteum is incised and separated from the bone with a raspator, all redundant periosteum being cut away. McEwen's triangle is located, and a retractor inserted, so as to pull the pinna forward. All the vessels on the posterior flap are clamped, while those on the anterior are compressed by a small wad of cotton-wool under the retractor.

A hole is then bored over McEwen's triangle with a hand gouge 11 mm. in diameter. The boring is continued in a direction which cannot be previously defined, as it must follow the line of least resistance, skirting in front of the lateral sinus. There is a thin dense wall of bone lining the sinus, which can always be seen as a dark blue mark. Finally, depending upon

the anatomy of each case (and all are different), an occasional cell is reached about 10 mm. from the surface; though less frequently there are cells 2 mm. from the surface. The 11 mm. gouge is used till a thinness is noticed at the bottom of the boring. A 7 mm. gouge is now used, and the boring, or rather filing or scraping process, is continued until the thin wall of the antrum, or attic of the middle ear, is reached and gently scraped away. The first opening to appear is probed to discover whether it is only a cell or a larger cavity leading into the middle ear; the excavation is continued till a definite opening of about 5 mm. diameter is produced. A strong probe with a short right-angle bend is inserted and the thin wall between the antrum or middle ear (as the case may be) and the boring is broken away by pulling outwards. A fine probe, bent at an angle of 45° at the tip, is carefully passed at the bottom of the boring towards the middle line to ascertain if the attic of the middle ear has been entered. Great care is taken not to disturb the processus gracilis of the malleus. The total depth from the surface of the skull to the bottom of the attic is 22 mm.

The posterior portion of the cartilaginous canal is now separated from the osseous canal, and the ridge of bone between this canal and the boring is scraped away with the 11 mm. gouge for about 5 mm. The cartilaginous canal is divided transversely at the level of the ridge and two longitudinal incisions are made so as to reflect a flap of the canal outwards. A broad director is inserted through the external auditory meatus under the flap, and the incisions are continued, till the external auditory meatus will admit the tip of the little finger.

The flap is now sewn with catgut to the under surface of the reflected skin, so as to keep the widened meatus patent, and stop bleeding.

Two suitable rubber tubes are now inserted from the external meatus to the bottom of the boring.

The incision at the back of the ear is closed with horse-hair, a small opening being left at the bottom for drainage. The ear is smeared with carbolised (1 per cent.) vaseline and a dressing applied behind it.

A hammer is never used as the bone is extraordinarily variable in density. In old-standing cases it is ivory-hard and there are no cells, while the lateral sinus forms a bend towards the external auditory canal. The facial nerve runs no risk, while the lateral sinus can always be seen. The dura mater is occasionally seen when the bone is very dense; this is when the cranial cavity comes lower down than usual, to fill the space normally occupied by the mastoid cells.

After-treatment.

The tubes are syringed out and one is removed on the first day; on the second day the remaining tube is removed and the cavity plugged with narrow ribbon gauze. The gauze is removed twice a day and the cavity syringed out either with 1 in 4000 perchloride of mercury or with biniodide, or with a weak solution of hydrogen peroxide, or hypochlorite.

By the end of a week the cavity discharges a good deal of mucus. The orifice is kept patent with gauze plugging, which is renewed once or twice a day for three weeks. On each occasion that the plugging is removed the cavity is syringed out with a weak antiseptic. Special care should be taken to inspect the bottom of the boring with an auroscope, so as to keep the foramen open which enters the middle ear; this is about 18 mm. from the surface. By the end of the third or fourth week mucous membrane lines the boring and joins with the skin of the external auditory canal. After a month or so the patency of the external opening is maintained by using a large lacrimal probe. The patient usually goes home at the end of the third or fourth week. A thin membrane, almost like tissue paper, often forms across the opening after some weeks and may require to be pierced every now and then if the hearing diminishes.

The result of the operation is to produce a new air passage to the middle ear. This incidentally opens

the Eustachian tube, as the middle ear is now no longer a closed cavity, and so the patient can easily blow air through the Eustachian tube via the middle ear and out by the extreme auditory meatus. The middle ear is also drained, and the mucous membrane rendered healthy.

Results.

I have operated on more than 200 cases, from the ages of 4 to 70 years. The results have been variable, depending upon the period of the deafness. The improvement in the hearing of many patients who have been deaf for 30 years has been astonishing, and no case has ever been worse after the operation. In many the deafness has been arrested, while in the great majority the hearing has been greatly improved.

An Operation for the Alleviation of Deafness.

Lancet, December 31st, 1927, p. 1417.

The following letter appears in the *Lancet*:—

SIR,—Major Vincent Nesfield's article on this subject (*THE LANCET*, Dec. 24th, p. 1338) is most interesting to me. Had he been an aural, and not an ophthalmic, surgeon he might have known of the mastoid operation I introduced in 1906—of which thousands have been performed—on practically the same lines as the operation he now outlines. My operation, also, was outlined in your issue of August 11th, 1906; the ten cases there described (all that had then been performed) were exhibited by me at a meeting of the British Laryngological, Rhinological, and Otological Association (the Royal Society of Medicine was not then in existence). Their perforated drums had healed and their hearing was so good (some absolutely perfect) that I received unanimous congratulations. The report of this meeting was published in your issue of Dec. 15th, 1906.

The great ear hospital at The Downs, Sutton, has, at this moment, 150 operations of this kind now in the wards. I was operating there two evenings ago. I hope when Major Nesfield exhibits his cases—as, of course, he will—that the results will justify his audience in also giving congratulations, for there are too many deaf people in this country.

I am, Sir, yours faithfully,

CHARLES J. HEATH, F.R.C.S. (Eng.).

Consulting Aural Surgeon, The Downs Hospital; late Surgeon, Throat Hospital, Golden-square, W.

Dec. 26th, 1927.

Reviews.

RECENT ADVANCES IN TROPICAL MEDICINE.—

By Sir Leonard Rogers, C.I.E., M.D., F.R.S.
London: J. & A. Churchill, 1928. Pp. 400, with
12 illustrations. Price, 12s. 6d. net.

If Sir Leonard Rogers had merely given an account of his own contributions to tropical medicine they would be well worth putting together in a volume like this, but we are further indebted to him for having included an admirable account of the work of many other investigators.

Sir Leonard has written the excellent articles on tropical diseases which have appeared for the past few years in the *Medical Annual*, and now he has brought together the substance of these articles and added to them in such a way as to produce a book which will be greatly valued by all students of exotic diseases.

In the 400 pages of this handy volume the student will find exactly what he wants to know of the recent advances in tropical diseases; there is no padding, no inclusion of unnecessary details, and no omission of anything that is important. The whole of the literature has been studied and summarized by an expert

who is thoroughly competent to separate the wheat from the chaff. There is no need to advise the worker in the tropics to buy the book, he simply must have it, but we appeal to the small army of writers of text-books of general medicine to make themselves familiar with its contents and so avoid the common mistake of giving misleading and obsolete accounts of diseases of which they have no personal experience. Although Sir Leonard might justly ignore much of the work which has been done by lesser men, he has been exceedingly generous in doing justice to their contributions. He writes in the manner of a critic, but he is a generous and friendly critic who gives the fullest consideration to views which must in some cases be different from his own.

A strict sense of proportion is maintained throughout the book, and special prominence is given to the important diseases, their diagnosis and treatment.

The book will be read with great pleasure and profit by every medical man who wishes to handle his cases of tropical diseases with efficiency: it will also be essential for constant reference regarding the doubts and difficulties which arise in everyday practice.

The book has been produced in an excellent manner by the publishers, who are to be congratulated on having persuaded Sir Leonard to place his unique knowledge at the disposal of the medical men who have to deal with cases of tropical disease.

J. W. D. M.

MEDICINE MONOGRAPHS, VOL. X. "THE SIGNIFICANCE OF THE PHYSICAL CONSTITUTION IN MENTAL DISEASE."—By F. I. Werthelmer and Florence E. Hesketh. London: Baillière, Tindall & Cox, 1926. Pp. xiv plus 87, with 30 plates. Price, 11s. 6d. net.

THIS latest addition to the series of *Medical Monographs* traces the development of the conception of body types and their relation to mental function and mental disease. The aim of the authors is to give a concise critical analysis of the various anthropological methods, particularly those which relate to medicine and psychiatry, and in addition to present a new anthropometric index. Current conceptions of personality are evaluated and discussed from a new point of view. The authors present a study of a series of patients with reference to body type and make an attempt to correlate psychoses and personalities according to their index and classification of body types. Dr. Lewellys Barker has contributed a preface in which he discusses the study as an addition to our knowledge of the "biology of the person," recommending it warmly to all students of internal medicine and psychiatry. The volume is illustrated with twenty figures in the text and five plates. It has a working bibliography of ninety-five references and a full index. The book should prove useful to anthropologists, psychiatrists, and to the ever increasing body of practitioners of medicine who are becoming more and more interested in the relationship of constitution to disease, a subject which is in the forefront of medicine to-day.

O. B.-H.

AFFECTIONS OF THE STOMACH.—By Burrill B. Crohn, M.D. London and Philadelphia: W. B. Saunders Company, Ltd., 1927. Pp. 902, with 361 illustrations, some in colours. Price, 45s. net. Agents in India: Messrs. Thacker, Spink & Co., Calcutta.

THIS book is a monograph on diseases of the stomach; it deals with the subject from the point of view of laboratory examination as well as from that of the clinician. It is essentially a book for the specialist or for reference for the general practitioner. One of the most valuable chapters is on the radiography of the stomach, by the author in collaboration with Dr. S. J. Goldpart; others which are of special importance are those dealing with gastro-duodenal ulcers, in which will be found a critical analysis of the results which are obtained by medical and surgical treatment respectively. It must be admitted that the

practitioner will not derive great comfort from these chapters. Dr. A. A. Berg tells us that the only operation which brings about a permanent cure is sub-total gastrectomy, a procedure which will be undertaken by few surgeons in India in spite of the author's claim to a mortality of less than 5 per cent. in 400 cases. Medical treatment is said to bring about a cure in about 50 per cent. of cases provided that prolonged and careful treatment is adopted. As a whole the book is one of very great value, but it is by no means a beginner's text-book; it deals with the whole subject in a spirit of scientific caution, and consequently there is a complete absence of the simple dogmatism which appeals so strongly to the student as well as to the average practitioner. The illustrations are very good, and the price reasonable.

CHOLERA CHIKITSA (IN BENGALI).—By Arun Kumar Mukherjee, M.B. (Cal.). Second Edition. Published by B. C. Bhattacharyya, 23-B, Bethune Row, Calcutta, 1928. Pp. 108. Illustrated. Price, Re. 1-8.

THE second edition of this little illustrated booklet on cholera by Dr. Arun Kumar Mukherjee is to be highly recommended to doctors who are not very familiar with English, or who are more at home in the Bengali language. The book is a highly practical one and is written in a simple, clear style by one who has had abundant experience in dealing with the disease. The diagnosis and prevention of cholera are fully dealt with, and its treatment along the lines advocated by Sir Leonard Rogers is very lucidly explained. This little book will be very acceptable in the villages of Bengal where epidemics of cholera are so frequent.

E. M.

THE TREATMENT OF FRACTURES—WITH NOTES UPON A FEW COMMON DISLOCATIONS.—By Charles Locke Scudder, A.B., Ph.D., F.A.C.S. Tenth Edition, Revised. Philadelphia and London: W. B. Saunders Company, Ltd., 1926. Pp. 1240, with 2,027 illustrations. Price, 55s. net.

THE tenth edition of this well-known text-book contains a revision of the subject matter, with enlargement of some of the chapters.

Special aspects of the subject, such as pathological fractures, birth fractures, fractures of the maxilla and mandible, bone repair and massage, are dealt with by separate contributors.

The much-discussed subject as to the place occupied by open operation in the treatment of fractures is very fairly dealt with. The experience of the Great War proved, and subsequent work has confirmed, that traction methods can produce ideal anatomical apposition, with good functional results. It is not necessary to employ various assortments of hardware as internal fixation devices have been termed for the great majority of ordinary closed fractures.

It is inevitable that there should be certain fractures and conditions of fractures for which open operation is advisable. The author insists that proper experience is necessary in the choosing of these, and great technical skill is needed for their performance. The indications are clearly outlined. Sir Berkeley Moynihan's words, as quoted in the preface, that 'surgery to-day is being practised by too many light-hearted, and incompetent surgeons,' are becoming less applicable to ordinary surgery. But they may well be remembered in the case of open operations for the treatment of fractures.

About fifty pages only are employed in discussing some of the important dislocations.

Great stress is advisedly laid on the use of the simplest methods and apparatus for each case. We are also reminded that there is often no high road to success, and that alternative procedures may prove equally effective.

Scudder's *Treatment of Fractures* is now a well-established book, and needs no further reference here. It is a mine of information.

THE PRINCIPLES OF SURGICAL DRESSING.—By Lieut.-Col. R. C. McWatters, M.B., F.R.C.S. Calcutta and Simla: Thacker, Spink and Company, 1928. Pp. vi plus 110. Price, Rs. 3-8.

THE object of this small volume, as explained in the preface, is to gather together under one cover the important points in connection with surgical dressing—points very frequently dealt with in a somewhat casual fashion by the ordinary text-book of surgery. Let it be said that the author has on the whole succeeded admirably in his task. The subject matter is dealt with in clear, concise and logical fashion and case histories are given in several places to illustrate various points as they arise. There is a grateful absence of controversial topics and of errors we detected relatively few. We think, however, that the author's recommendation to irrigate the ear in otorrhœa with an ear syringe and boracic lotion (p. 74) will not meet with universal approval. On p. 77 the strength of physiological salt solution is given as 0.65 per cent. instead of 0.85 per cent.: this, however, is probably due to one of the printing errors from which the book is not entirely free despite its small size. To the student about to commence clinical surgery and also to the junior dresser Col. McWatters' little volume should prove of considerable service.

J. M. H.

CYSTOSCOPY.—By J. B. Macalpine, F.R.C.S. (Eng.). Bristol: John Wright and Sons, Ltd., 1927. Pp. 284, with 181 illustrations and 12 coloured plates. Price, 25s. net.

THERE has long been scope for a small hand-book on cystoscopy in English on the lines of Marion and Heitz Boyer's classical work in French. The present book appears to fill the gap admirably, it is not too lengthy, it deals with the subject from the practical aspect, the author has a wealth of experience to draw upon and as a teacher is able to appreciate the difficulties of the beginner. In the opening chapters the structure of the cystoscope is described in detail and the optical principles are lucidly explained and illustrated, dry matter but essential to be mastered if the cystoscopist is to get the best out of his instrument. The sections on how to track down faults should be carefully studied, as also the admirable scheme of examination laid down in Chapter III. Following the French School the author has a preference for sacral anaesthesia, a method which has not yet become very popular in England. The directions for dealing with irritable bladders, the figures showing how an incorrect position of the patient may introduce unnecessary difficulties, especially figure 51 showing various causes for failure to see anything in the bladder, and the description of the manipulation of the instrument during the actual examination so that nothing may be missed through lack of system, are all very practical and should be most useful to the beginner. The chapters on the various pathological conditions are on much the same lines as the corresponding chapters in Marion and Heitz Boyer, to which work the author pays due acknowledgment. It is difficult where all is so good to single out sections for special praise, but we consider that the chapters dealing with urteric catheterization, with the treatment of stones impacted in the lower ureter and with renal function tests are the clearest exposition of these subjects we have ever read. The simple scheme for estimation of kidney function which the author advocates is the one we have always considered the most suitable for conditions in this country, where expensive colorimeters are not numerous, and where tests which give an immediate answer are always to be preferred to those needing the intervention of a laboratory. The chapter on pyelography is very clear and is illustrated by numerous reproductions of typical pyelograms.

The illustrations, thanks to Mr. Thornton Shiells' well known skill, are beautifully drawn and coloured and give a realistic picture of the actual appearances.

As a whole the book merits unstinted praise; it is written in a pleasant style easy to read, it gives

all the information necessary to anyone except a specialist and it should take its place as the standard text-book. Most general surgeons have to use the cystoscope occasionally and sometimes run up against difficulties which render the examination valueless; such will not happen to those who have mastered the contents of this book.

W. L. H.

Annual Reports.

THIRD ANNUAL REPORT OF THE PASTEUR INSTITUTE, CALCUTTA, FOR THE YEAR 1926. BY CAPT. E. C. R. FOX, I. M. D., CALCUTTA, BENGAL SECRETARIAT BOOK DEPOT. 1927. PRICE RE. 1.

THE Pasteur Institute, Calcutta, was opened in 1924 in response to the incessant demand of the populace of Calcutta and Bengal for a local, provincial antirabic centre situated within the Province and more readily accessible than Shillong. It forms a section of the Calcutta School of Tropical Medicine, and is under the control of Capt. E. C. R. Fox, I.M.D., an officer with a life-long experience of antirabic work at Kasauli—where he was associated with Sir David Semple in the early days of antirabic work in India, Shillong, and Bombay. The amazing growth of this Institute can be judged from the following figures for patients treated:—

1924 (seven months)	.. 1,462
1925	. 4,168
1926	.. 5,141

Further, it is certain that the last figure would have been much larger, had it not been for the communal riots in Calcutta in April and May 1926, when the number of patients under treatment showed a rapid falling off in numbers. Despite these figures, Capt. Fox states that further increase in numbers is all too likely. The number of advice cases during the year was 1,432; the majority of these came from Calcutta, and the advice given saved them what would have meant a journey to Shillong had not expert advice been available on the spot in Calcutta. Thus the Institute has already much more than justified its existence.

The final figures dealt with in the statistical tables concern the 5,141 patients who completed treatment, and it is encouraging to note that from 80 to 85 per cent. of answers were received by the method of the follow-up postcard system. The total hydrophobia rate was 0.84 per cent. (43 cases), and this represents a quite appreciable lowering of incidence when compared with the general figures at Kasauli and elsewhere for many years,—probably owing to the very ready accessibility of Calcutta, and the early arrival of most patients. The failure rate was only 0.45 per cent. (23 cases).

Very interesting figures are given to show the entirely different degrees of risk among the European and Indian patients respectively. Thus the percentage of licks was 52 per cent. among the Europeans, as compared with 1 per cent. among the Indian patients; the average number of bites was 1.2 among the Europeans, as compared with 3.6 among the Indians; and only 23 per cent. of European patients had deep bites, as compared with 65 per cent. among the Indians. Eighty-eight per cent. of the European patients arrived with 24 hours of being bitten, as compared with 62 per cent. of the Indian patients: the latter figure, however, is an extremely good one for an Indian institute, and again emphasises the ready accessibility of the Calcutta institute; it is a very different figure from what used to obtain in the early days of the Kasauli institute.

The other tables in the report follow on the usual statistical lines. The hydrophobia rate for bites on the face, head, and neck was 6.32 per cent. among Indians,

as compared with the general rate of 0.88 per cent. Nearly 2,000 of the patients came from Bihar and Orissa, but that Province—we understand—is about to open an institute of its own, after having profited by the Calcutta experience. Jackal bites are prominent in the Calcutta (as in the Shillong) figures—a state of affairs quite different from what obtains in Burma and Coonoor. The hydrophobia rate in cases of jackal bite—1.5 per cent.—is nearly three times as high as in cases of dog bite—0.6 per cent. One patient who developed hydrophobia had been bitten by a rabid cat.

During the year, the work was carried on under most uncomfortable and very crowded conditions in a single laboratory on the fourth storey of the Calcutta School of Tropical Medicine; indeed the endless procession of the patients concerned up the main staircase of that institution every morning was a sight almost worthy of the Puri pilgrimage. Since then remodelling of the institution has been brought in, and the Pasteur Institute is now housed on the ground floor in better—but still inadequate—accommodation. The outside issue of antirabic vaccine was under consideration during the year, but in view of the expected report by the International Rabies Conference in Paris on this subject, and of the experimental work which is at present being carried out at the Pasteur Institute of India, Kasauli, on etherised vaccine, this question has been held in abeyance. The etherised vaccine is reported to be more efficacious than the present carbolic one, but has to be administered whilst fresh; a practice which would lead to reversion to the custom of treating all patients at a central antirabic station, instead of the outside issue of the vaccine to head-quarter hospitals, as now practised in some provinces in India.

Capt. Fox and his staff are to be congratulated on a year of steady work and progress, under most difficult conditions and with very inadequate accommodation.

KING EDWARD VII MEMORIAL PASTEUR INSTITUTE, SHILLONG. TENTH ANNUAL REPORT FOR THE YEAR 1926, BY MILITARY ASSISTANT SURGEON A. C. VARDON, I.M.D., SHILLONG. GOVERNMENT PRESS, ASSAM. PRICE RE. 0-12-0.

THIS report follows on the main statistical lines adopted by all the Indian institutes since its first introduction many years ago at the Kasauli institute by Lieut.-Col. W. F. Harvey, I.M.S. (retd.). The total number of patients treated during the year was 1,417—a definite increase on the figures for 1925. The total hydrophobia rate was 0.99 per cent. (14 deaths), and the failure rate 0.42 per cent. (6 deaths). Lick cases amounted to 77 per cent. among the European patients, as compared with 4.4 per cent. among the Indian patients. The vast majority of the patients—94.3 per cent.—came from Assam, whereas Bengal and Bihar and Orissa only contributed a few scattered cases. Jackal bites—always a prominent feature in the Shillong figures—accounted for no less than 12.3 per cent. of admissions, and yielded a hydrophobia rate of 5.2 per cent. as compared with a corresponding hydrophobia rate of 0.41 per cent. for patients bitten by dogs. Half the fatal cases occurred in persons bitten on the face.

A departure during the year was the issue of antirabic vaccine to veterinary and medical officers for the treatment of bitten animals in the Province. This brought in a sum of Rs. 500 to the Government revenues.

Turning to the bacteriological and research section, the routine tests carried out totalled 2,948. The kala-azar hospital attached to the Institute continued to carry out excellent work. A special feature of this work was the high proportion of non-kala-azar cases sent up for diagnosis as suspected kala-azar; of 167 suspected kala-azar cases admitted, only 56 turned out to be cases of that disease. In this respect there is

an immense difference between the reports of this Institute for 1917 and 1926. In the former year, when the hospital was first opened, kala-azar patients from the tea gardens had to be bribed to come to the Institute for treatment; in 1926 the majority of patients were resistant cases of kala-azar or cases presenting special difficulty in diagnosis, sent up for expert laboratory examination. The general populace in Assam is now not merely accustomed to intravenous injections for kala-azar; patients throughout the Province now demand the treatment, which is available at almost innumerable local centres near their homes; in place of typical, untreated cases of the disease, it is now the failures of treatment—or the patients suffering from diseases other than kala-azar, which seek the hospital at the Institute for treatment. Amongst such cases infection with intestinal helminths forms an important element in the clinical picture.

Lieut.-Col. F. C. Hodgson, D.S.O., I.M.S., was in charge during the year (except when absent on leave), but as he was transferred early in 1927 the present report is by Mr. A. C. Vardon, I.M.D., who took over charge from Colonel Hodgson, on the latter's transfer.

Correspondence.

THE MOFUSSIL DISPENSARY.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—Your interesting editorial in the December, 1927, number of the *Gazette*, on the *mofussil* dispensary, and your excellent suggestion of mobile motor medical attendance, or in the alternative of subsidy to private practitioners in preference to the badly equipped, poorly staffed *mofussil* dispensary of the present day, deserves the closest attention of all who have the good of the country at heart. A little consideration ought to show that in medical service mere quantity is no good; it is dangerous; the quality of service is what matters. I speak from personal experience as I come from a place situated far from any railway station, in what is generally regarded as the most insanitary subdivision in Bengal (Arambagh in Hoogli).

Your correspondent, Dr. Bhattacharyya, is wholly wrong when he says that "the illiteracy of the masses rather than the incapacity of the doctors concerned is the chief obstacle to the progress of modern scientific medicine." To do the Bengali peasant justice, he is always quick-witted enough when he finds a real remedy for his complaints. For example thirty years ago the treatment adopted for rabies was incantations, and occasionally a few secret reputedly potent remedies; we could not blame the peasant for it, as at that time scientific medicine held out little hopes of prevention or cure for rabies. As soon as Pasteur's treatment became known however and its effects recognised, these methods began to fall into disrepute and people began to take to the new treatment in right earnest. The only deterrent was the remoteness of the treatment centre, situated as it was at Kasauli, 1,100 miles away. The opening of a rabies treatment centre at the Calcutta School of Tropical Medicine has resulted in a much larger number of patients getting the treatment who would otherwise have been unable to avail themselves of it, and if more centres for the treatment of dog bite were opened in district headquarters, as they ought to be, there would be no dearth of patients or attendance.

Cholera furnishes another example of how success in treatment can win over even village people to the most complicated and difficult methods of treatment. Twenty-five years ago on our own showing our treatment of cholera resulted in 70 per cent. of deaths, and it was the exception for a villager to take allopathic treatment when attacked with cholera. Now it is the exception to do otherwise. The expenses incurred in

getting the most up-to-date treatment for cholera with repeated intravenous injections and rectal injections are however too much for the poorer agriculturists. It is mostly on this score and owing to the want of properly qualified medical officers willing and able to carry out proper treatment, and also to the absence of a specific cure, which is largely responsible for the people still occasionally taking to other methods of treatment.

Lastly kala-azar furnishes a brilliant example of how a complicated method of treatment, often painful, always tedious, and generally expensive, can completely win over the so-called ignorant villagers in less than a decade. How can we blame them, if in the pre-antimony days, when the mortality figures stood at somewhere about 90 per cent. they would fight shy of our system. Now that the death rate is only 10 per cent. there is no dearth of patients at the kala-azar centres and District Boards are vying with one another in issuing free supplies of the newer antimony preparations.

I have purposely selected rabies, cholera, and kala-azar for illustration—three diseases in which the course of treatment is one long series of injections. It has been especially in these three that modern medicine has achieved an unusual degree of success in India. I cannot help quoting here the experience of a friend and colleague of mine, a young Bengali Mahomedan graduate who started practising in his native village in the 24-Perganas district, an out of the way place with mostly poor cultivators in the neighbourhood. He says as soon as his first kala-azar case became cured and the first dysentery case improved with emetine, men began to talk about it in the bazar and in six months' time his house continually resembled a *mela* full of the sick and the infirm, their friends and relatives of all the villages for miles around. Unfortunately for the villagers, the doctor had to leave the village as he and all the members of his family were repeatedly attacked with malarial fever.

It is only in the diseases in which we do not claim a cure such as nervous affections, paraplegia, hemiplegia, chronic rheumatic trouble, cirrhosis of the liver, mental diseases, etc., that the villagers will try other systems of treatment, or as a last resort faith healing.

Indeed instead of the cultivator resenting injections, how often have we not seen a villager coming to us and requesting us not to use our drugs but our 'injunctions' (!) as he often chooses to pronounce it?

The remedy, therefore, lies in improving our own methods and improving the quality of service. As I say, it is not the ignorance of the villagers or their superstition but the inefficiency of our medical service, starved of training and of funds which forms the principal drawback to progress in therapeutics in the *mofussil*. What is wanted is money and even more than money, a policy, a co-ordinated comprehensive policy for the province and possibly for India as a whole.—Yours, etc.,

SANAT KUMAR GUPTA, M.B.

124/4, MANIKTALA STREET.

Calcutta, 12th January, 1928.

THE CHEMISTRY OF THE BLOOD OF NORMAL HEALTHY INDIANS.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—In the July, 1927, issue of the *Gazette* there is an interesting paper by Dr. J. P. Bose on the chemistry of the blood of Indians. In his article Dr. Bose does not make any reference to my previous work on the same subject. Perhaps he is unaware of the work I have been carrying on for the last four years, though in view of the fact that most of my papers were published in the *Calcutta Medical Journal* (March and September, 1923; May and October, 1925), it seems improbable.

Dr. Bose's findings are more or less similar to mine. His figure for the normal uric acid content of the blood is, however, rather lower than my findings, though he has not mentioned what method he employed. Benedict's recent method generally gives higher results than Folin's older method. Using both methods it was found that the uric acid content of the blood of healthy Bengalees is higher than the corresponding normal figures for Europeans.

My findings are given below, the subjects being healthy young male students:—

	Maximum.	Minimum.	Average.
1. Non-protein nitrogen	35.0 mgm. per 100 cc. of blood.	22.0 mgm. Per 100 cc. of blood.	27.4 mgm. per 100 cc. of blood.
2. Urea nitrogen	15.0 mgr. "	8.4 mcm. "	11.2 mgm. "
3. Uric acid { (a) by Benedict's new method	5.6 mgm. "	3.6 mgm. "	4.6 mgm. "
(b) by Folin's old method.	4.0 mgm. "	2.2 mgm. "	2.9 mgm. "
4. Cholesterol	160 mgm. "	124 mgm. "	140 mgm. "
5. Calcium	10.2 mgm. Per 100 cc. of serum.	9.2 mgm. per 100 cc. of serum.	9.6 mgm. per 100 cc. of serum
6. Creatinine	1.46 mgm. per 100 cc. of blood.	0.8 mgm. per 100 cc. of blood.	1.08 mgm. per 100 cc. of blood.
7. Blood-sugar	120 mgm. "	50 mgm. "	99 mgm. "
8. Inorganic phosphate	3.58 mgm. Per 100 cc. of plasma.	2.36 mgm. per 100 cc. of plasma.	3.0 mgm. per 100 cc. of plasma.
9. RPH (blood)	8.65	8.45	8.5

THE INCUBATION PERIOD OF MEASLES.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—I would like to draw the attention of your readers to the period of isolation for measles, which has been the subject of correspondence in recent issues of the *British Medical Journal*.

When such high authorities as Dr. W. E. Goodall and Dr. J. D. Rolleston agree that it is perfectly safe for an uncomplicated case of measles to mix in society fourteen days after the first appearance of the rash, there should be no matter for doubt.

10. Sedimentation Velocity average (male)—7.6 mm. per hour during first hour; (column of blood 100 mm. long, calibre of tube—11 mm.; 4 volumes of blood mixed with 1 vol. of 3.8 per cent. sodium citrate solution).

11. Basal metabolic rate average—9 per cent. (compared to European standards).—Yours, etc.,

H. N. MUKHERJEE, B.Sc., M.B., D.L.C. (London).

BIOCHEMICAL DEPARTMENT,
CARMICHAEL MEDICAL COLLEGE,
1, BELGACHIA ROAD,
Calcutta, January 18th, 1928.

In an outbreak of 100 cases of measles in this school in 1926, the uncomplicated cases were discharged back to School from Hospital after a fortnight, and I was not able to trace fresh infections to such action.

In consequence, we were able to deal with this epidemic without undue strain on our limited isolation accommodation and nursing staff.

The number of school hours not lost is apparent, and the advantage of not having an accumulation of virile children to diet and amuse for an extra week, can only be appreciated by those who have to do it.—Yours, etc.,

P. SAVAGE,

MAJOR, I.M.S.,

Resident Medical Officer.

THE LAWRENCE ROYAL MILITARY SCHOOL,
SANAWAR, SIMLA HILLS,
13th February, 1928.

Service Notes.

APPOINTMENTS AND TRANSFERS.

Lieutenant-Colonel R. W. Anthony, M.B., C.M., F.R.C.S.E., I.M.S., Officiating Surgeon-General with the Government of Bombay, is confirmed in that appointment, with effect from the 10th January, 1928.

Lieutenant-Colonel F. E. Wilson, I.M.S., Civil Surgeon, Quetta, is appointed to Officiate as Residency Surgeon and Chief Medical Officer in Baluchistan, in addition to his own duties, with effect from the 1st January, 1928.

Lieutenant-Colonel J. Husband, I.M.S., an Agency Surgeon, on return from leave is posted as Legation Surgeon, Nepal and ex-officio Assistant to the British Envoy at the Court of Nepal, with effect from the 24th January, 1928.

Lieutenant-Colonel R. Knowles, I.M.S., Professor of Protozoology, School of Tropical Medicine and Hygiene, Calcutta, is appointed to act, until further orders, as Director of the School, in addition to his own duties.

Lieutenant-Colonel A. D. Stewart, I.M.S., Professor of Hygiene, School of Tropical Medicine and Hygiene, Calcutta, is appointed to act, until further orders as Principal, Medical College, Calcutta, in addition to his own duties, with effect from the date on which he takes over charge.

Lieutenant-Colonel W. L. Harnett, M.B., F.R.C.S., I.M.S., Superintendent, Campbell Medical School and Hospital, is appointed to act as Professor of Clinical and Operative Surgery of Medical College, Calcutta, and Surgeon to the College Hospital, *vice* Lieutenant-Colonel H. B. Steen.

Lieutenant-Colonel H. B. Steen, M.D., I.M.S., Officiating Professor of Clinical and Operative Surgery, Medical College, Calcutta, and Surgeon to the College Hospital, is appointed to act as Professor of Surgery, Medical College, and Surgeon to the College Hospital, *vice* Lieutenant-Colonel Sir F. P. Connor, Kt., D.S.O., going on leave.

Lieutenant-Colonel J. D. Sandes, M.B., F.R.C.P.I., I.M.S., is appointed to act until further orders as Professor of Medicine, Medical College, Calcutta, and First Physician, Medical College Hospital.

Major C. H. Smith, O.B.E., I.M.S., an Agency Surgeon, on return from leave, is posted as Agency Surgeon in Bundelkhand, with effect from the 23rd January, 1928.

Major H. G. Alexander, F.R.C.S., I.M.S., on return from leave, is appointed to act as Police Surgeon, Calcutta, *vice* Major J. C. De.

Major J. C. De, M.B., I.M.S., Police Surgeon, Calcutta, is appointed to act as Professor of Clinical Medicine, Medical College, Calcutta, and Second Physician, College Hospital, *vice* Lieutenant-Colonel J. D. Sandes.

Major S. N. Mukherjee, F.R.C.S., I.M.S., Officiating Civil Surgeon, Chittagong, is appointed to act as Superintendent, Campbell Medical School and Hospital, Calcutta, *vice* Lieutenant-Colonel W. L. Harnett.

Major S. A. McSwiney, M.B., F.R.C.S.I., I.M.S., is appointed to act as Civil Surgeon, Chittagong, *vice* Major S. N. Mukherjee, transferred.

LEAVE.

Colonel J. D. Graham, C.I.E., I.M.S., Public Health Commissioner with the Government of India, is granted leave on average pay for 8 months, with effect from the 23rd March 1928 or subsequent date on which he avails himself of it.

Lieutenant-Colonel C. B. McConaghy, I.M.S., an Agency Surgeon, is granted leave on average pay for 8 months combined with leave on half average pay for 20 months, under the Fundamental Rules, with effect from the 24th January, 1928.

Lieutenant-Colonel Sir F. P. Connor, Kt., D.S.O., F.R.C.S., Professor of Surgery, Medical College, Calcutta, and Surgeon to the College Hospitals, is granted leave from the 29th February 1928 to the 15th December 1928.

Major F. R. Thornton, M.C., I.M.S., Civil Surgeon, Coorg, is granted leave on average pay for 8 months, with effect from the 16th March 1928 or subsequent date on which he avails himself of it.

PROMOTIONS.

Lieutenant-Colonel to be Colonel.

L. J. M. Deas, M.B., F.R.C.S.E., *vice* Colonel R. W. Knox, D.S.O., M.B., F.R.C.S. Dated 1st January, 1928.

Majors to be Lieutenant-Colonels.

W. E. Brierley, M.B., F.R.C.S. Dated 1st February, 1928.

J. B. Lapsley, M.C., M.B. Dated 1st February, 1928.

C. H. Fielding, M.B. Dated 1st February, 1928.

W. L. Watson, O.B.E. Dated 1st February, 1928.

H. C. Tait, M.B.E., M.B. Dated 2nd February, 1928.

J. C. Chukerbuti, M.B. Dated 17th February, 1928.

The provisional promotion of the undermentioned officer to the rank of Captain as notified in Army Department Notification No. 1225, dated the 24th September, 1926, is confirmed, subject to His Majesty's approval:—

W. Lawie, M.B.

RESIGNATION.

Lieutenant T. D. Donegan, I.M.S. Dated 31st December, 1927.

RETIREMENTS.

Lieutenant-Colonel T. H. Gloster, M.B., I.M.S. Dated 25th August, 1927.

Colonel G. Browse, D.S.O., M.D., I.M.S. Dated 27th December, 1927.

Lieutenant-Colonel W. W. Jeudwine, C.M.G., M.D. Dated 1st January, 1928.

NOTES.

BOVRIL, LTD.

On the 25th and 26th October 1927 nearly 3,000 doctors from all parts of Great Britain visited the Bovril Factory in Old Street, London. Every country contributed its quota, including doctors from the far North of Scotland, and the remote parts of Devon, Cornwall and Wales.

The visitors were welcomed by Sir George Lawson Johnston (Chairman), The Duke of Athol, K.T. (Vice Chairman), Sir James Crichton-Browne, M.D., LL.D., F.R.S., Lieut.-Gen. Sir A. T. Sloggett, K.C.B., K.C.M.G., K.C.V.O., and other Members of the Bovril Board, and were then conducted in parties over the premises. They were much impressed by the brightness and airiness of the whole spacious building, and by the strictly hygienic conditions under which Bovril is made, as well as by the ingenious machinery which enables the Company to turn out annually so many millions of the familiar brown bottles. The splendidly equipped laboratories were particularly admired.

The processes of manufacture were followed with much interest, from the blending of the extracts and essences in the great steam jacketed pans, each capable of holding the concentrated juice of 300 oxen, and the incorporation with these of the beef fibrin and albumen which are so important a factor in the nutritive value of Bovril, to the automatic filling, capping labelling and boxing of the bottles. The finished Bovril is conveyed by pipes to the filling machines from the great storage tanks on the floor above, each of these wonderful machines being capable of filling 400 gross of bottles per day.

Lunch followed the tour of inspection. The final item in the programme, which was also much appreciated, was a cinematograph display of scientific films illustrating the activities in the blood of various micro-organisms.

COMMON HELMINTHS IN MEDICAL PRACTICE.

THIS is the title of a little booklet issued by the Scientific Department of the Eastern and Russian Trading Co., Ltd., London; the agents for santonin. It is well illustrated and deals with the life-histories of *Ascaris lumbricoides*, *Oxyuris vermicularis* and *Trichuris trichiura*. Much recent work is referred to, and there is a useful little bibliography at the end of each chapter. The concluding chapters deal with pathogenicity; treatment by santonin and purgation; and give a historical review of the work on santonin.

We understand that copies of this little booklet are available free from the Bombay Agent of the firm; G. S. Mahomed, 164, Samuel Street, Bombay; also from the Calcutta Agents, Messrs. Turnbull Bros., P. O. Box No. 289, 112, Hare Street, Calcutta.

'HYPOLOID' QUININE IN MALARIA.

QUININE BIHYDROCHLORIDE is widely used in malaria. It is preferred to other quinine salts for several reasons, particularly because it contains a high percentage of pure alkaloid, is very readily soluble and quickly absorbed.

When it is desired to administer quinine bihydrochloride by the most direct route, i.e., by injection, 'Hypoloid' quinine bihydrochloride possesses special advantages. This product presents an accurate dose of the pure salt in sterile solution, in a hermetically-sealed glass container made from specially-tested neutral glass which does not exert any injurious action on the contents.

'Hypoloid' quinine bihydrochloride is extremely suitable for the purpose of obtaining a rapid anti-

malarial action, and is always ready, in a sterile condition, for immediate injection.

One of the great advantages of all 'Hypoloid' products is that they can be brought into action instantaneously, at the moment their use is indicated. The amount of time required to make the injection, so vital a consideration on occasions, is negligible.

'Hypoloid' quinine bihydrochloride is available in four metric strengths, 0.2-gm., 0.4-gm., 0.6-gm. and 1 gm. The products are issued in boxes of 10 by Burroughs, Wellcome & Co., London.

SULPHOSTAB-BOOTS.

It is recognised that in the modern treatment of syphilis the exhibition of arsenic in organic form is essential. The most rapid results are obtained by the intravenous route, but more lasting effects follow the giving of arsenic intramuscularly. On the other hand intramuscular administration is apt to be followed by the formation of painful lumps at the site of injection. Hence the need for a safe arsenical which can be administered subcutaneously. Further, such a compound is especially wanted for the treatment of congenital syphilis in infants.

Messrs. Boots claim that in their 'Sulphostab-Boots' such a product is available. It has been placed on the approved list of the British Ministry of Health. Sulphostab-Boots is a yellow powder packed in sterile ampoules ready for dissolving in sterile water, and it is stated that its subcutaneous administration is painless and is not accompanied by any reaction at the site of injection. It is of special value in the treatment of congenital syphilis, in syphilitic carditis where a high concentration of organic arsenic in the blood is undesirable, and for disseminated sclerosis and chronic skin lesions where organic arsenic is often of value.

In the treatment of congenital syphilis one course—each of six weekly injections, rising from 0.10 gm. to 0.20 gm. with the rise of age from birth to 2 years—given for two consecutive years is advised; whilst three different courses are outlined for adults, in cases of primary, secondary and tertiary syphilis respectively. The course of injections of Sulphostab can be accompanied by a course of bismuth, e.g., such a preparation as Bismostab-Boots.

Publishers' Notice.

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles will receive 25 reprints *gratis*, if asked for at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions, Advertisements, and Reprints should be addressed to THE PUBLISHERS, Messrs. Thacker, Spink & Co., P. O. Box No. 54, Calcutta.

Annual Subscription to "*The Indian Medical Gazette*," Rs. 16 including postage, in India. Rs. 18 including postage, abroad.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

KOLYNOS

DENTAL CREAM

CHOOSING A DENTIFRICE.

FLAVOUR is most important when considering a dentifrice, because the frequency of its use is directly proportional to the attractiveness of its taste.

Children readily brush their teeth when Kolynos Dental Cream is recommended because they appreciate the delightful flavour. The clean feeling after its use appeals to adults and to children alike.

As a professionally trained man, acquainted with the formula, the dentist knows that Kolynos cleans the mouth mechanically, chemically, and bacteriologically. The patient knows only by the clean and refreshing feeling.

On request our Distributors will gladly send you a dental package, free of charge.

Bombay, No. 1

MAKE MILK DIGESTIBLE

When an infant is fed on cow's milk (or milk and water) it is well known that the milk forms a clot on reaching the stomach. The clotted milk is difficult to digest—it is often the cause of stomach disorders, and the infant may fail to thrive. The photographs reproduced here were taken in our own physiological laboratory—they prove in a graphic way the power of Robinson's "Patent" Barley in breaking up the tough, indigestible clot of ordinary cow's milk.

Fig. 1.—Shows the indigestible clot formed with an equal bulk of *plain water*. Robinson's "Patent" Barley prevents the clot and makes milk digestible.

Fig. 2.—Shows the effect of adding the slightest trace of Robinson's "Patent" Barley to cow's milk. The indigestible clot is effectively broken up—milk is made more digestible.

Fig. 3.—Shows the finely divided precipitate formed in the stomach of an infant fed on cow's milk properly diluted with Robinson's "Patent" Barley. The precipitate of mother's milk is just like this—Robinson's "Patent" Barley makes milk digestible.

ROBINSON'S "patent" BARLEY

Makes cow's milk into the perfect baby food.

The directions on every tin must be carefully followed.

THE TREATMENT OF FRACTURE OF THE FEMUR.

By W. L. HARNETT, M.A., M.B. (Cantab.),
F.R.C.S. (Eng.),

LIEUT.-COL., I.M.S.,

Officiating Professor of Clinical Surgery, Medical College, Calcutta.

A CYNICAL old London surgeon is supposed to have told his class that the best way to treat a fracture was to send the case to the rival practitioner in the same street. Those who can recall the treatment of fractures as taught twenty years ago, with its inefficient fixation by wooden splints and the resulting overlapping and angulated fragments, wasted muscles, stiffened joints and shortened, often permanently crippled limbs will be disposed to agree that the advice quoted above, if cynical, was at any rate sound common sense. The practitioner had nothing to gain and everything to lose in reputation by handling these cases: if the result was tolerably good it was attributed to the patient's good constitution and the remarkable mending power of his bones, whilst if, as more often happened, the appearance and function of the limb left much to be desired, the practitioner would be apt to find himself talked about in the neighbourhood as a bungler and perhaps involved in costly litigation. In hospital the visiting surgeons with rare exceptions relegated these cases to the care of their house surgeons, who, with the humility natural to youth in those days, supposed this to imply that the great man looked on such trivial cases as beneath his notice. The real reason was quite otherwise; the surgeon knew that he was not likely to achieve any better result than his house surgeon would, so he had no more inducement than had his colleague in general practice to undertake a thankless task. It is no wonder that Lane's new teaching of operation in all these difficult cases was received with acclamation and appeared likely at first to revolutionise the whole subject. But it was soon discovered that Lane's imitators did not always possess his mastery of technique, and the pros and cons of operative treatment of fractures were still the subject of lively discussion at medical societies when the war enabled the matter to be investigated on a vast scale. The result has been such an improvement in methods of treatment by traction, that the field for operative interference has been narrowed down till it embraces little more than the cases where great displacement has refused to yield to traction, and certain other cases to be referred to later. Most of these improvements

centre round the manifold uses which have been made of Thomas' knee splint, for which the credit is mainly due to Major Sinclair, R.A.M.C., and to the inspiration of Sir Robert Jones.

Fractures of the femur present a more difficult problem of treatment than those of any other bone in the body. It is the largest and longest bone, it lies deeply buried in soft parts, the powerful muscles attached to it exercise a great distorting influence, its adequate repair requires that it should be restored to its full length and correct alignment as it has to act as one of a pair, and lastly it has to support the full weight of the body on a skeletal strut which is normally curved and which tends to bend under the body weight if the reparative material is not perfectly solid. All the efficient methods of treatment may be divided into three great groups:—

- (a) Treatment by abduction.
- (b) Treatment by traction with or without abduction.
- (c) Treatment by open operation.

It is not proposed in this article to do more than indicate the class of cases suitable for the third method of treatment, without describing the details of operative technique, nor will more than a passing reference be made to compound fractures. Out of the multiplicity of methods of the first and second classes available the writer has endeavoured to select for description those which in his own hands have given the best results with the simplest appliances.

FIRST AID TREATMENT.

Only too often the original fracture, serious as it is, is made incomparably worse by inefficient efforts to move the patient and by transport without adequate fixation. The sharp bone ends may be thrust into muscle, extravasation of blood increased, and perhaps important vessels injured with consequent danger to the life of the limb from pressure and to that of the patient from increase of shock. If nothing else but pieces of wood and some improvised triangular bandages are available, the excellent method taught in the first aid classes and described and figured in the *Manual of First Aid* should be adopted. The ideal method however is the use of the Thomas' knee splint, which should be available at all first aid posts. A splint of suitable size having been selected by measurement of the circumference of the thigh at the gluteal fold outside the trousers, the injured limb is grasped near its extremity and a gradually increasing pull is exerted. Maintaining extension on the angle all the time, the leg is threaded through the ring of the splint without removing the trousers, until the ring rests snugly against the tuber ischii. An assistant

then takes a 6-inch roller bandage, ties the end to the outer bar of the splint near the ring and passes it behind the thigh from side to side over the inner bar, then back and over the outer bar and so on until the whole of the posterior aspect of the limb is supported. A noose of bandage is applied round the ankle over the boot and tied to the end of the splint with sufficient tension to maintain the requisite extension. Sinclair's "boot clamp" or a *skerwer* thrust through the upper of the boot between the sole of the foot and the sole of the boot, with tapes attached to tie to the end of the splint are more efficient methods of maintaining extension and are to be preferred if available. The patient is lifted on to a stretcher which should be fitted with a "suspension bar" to which the side bars of the splint are slung to prevent the side bars from falling back and forcing the limb too far forward, which would increase the deformity and cause pain. An alternative plan is to rest the end of the Thomas' splint below the sole of the boot on some form of support such as rolled up clothing. Only after the limb has thus been securely fixed should the clothing be cut away at the site of fracture to deal with any wound which may be present. Finally, a firm pad should be placed on each side of the knee between the limb and the side bars, and the leg and splint bandaged at this level to give greater security. Cotton-wool should be padded in the space between the thigh and the ring to prevent the ring from slipping upwards or inwards and losing its purchase against the tuber ischii. The patient is now ready for transport and the apparatus should not be further disturbed until the patient is in hospital or nursing home and the permanent extensions are substituted. If a long journey has to be taken it is well to remember that temporary extension taken from a boot should not be too great or persisted in too long, lest pressure of the boot cause obstruction of the dorsalis pedis artery and ulceration or even gangrene. Morphia and warmth are of course indicated to combat shock and pain during transport.

TREATMENT BY ABDUCTION.

Fig. 1 shows the usual sites of fracture at the upper end of the femur. No. 1 lies at the border between the head and neck, but is sometimes situated a little lower at 2. This is called the subcapital fracture and is always intracapsular. The shortening is not great (about $\frac{1}{2}$ — $\frac{3}{4}$ inch) and the limb is everted and adducted. This is the fracture which is notable for the great frequency with which it fails to unite. This tendency used to be attributed to old age, but this is not correct because the fracture unites quite well in old people if properly treated, and is just as obstinate with regard to non-union in a young

man as in an old one if special treatment is not adopted. The causes of non-union are in order of importance (1) defective blood supply of the upper fragment; (2) defective apposition of the fragments; (3) interposition of torn portions of the capsule; and (4) the inhibitive influence of the synovial fluid depositing a fibrous surface on the raw bone and so sealing up its cellular elements. If the fragments are firmly and accurately apposed, bony union will take place with certainty, but if correct treatment is delayed rapid atrophy of the proximal fragment will occur and within a few months all that part of the neck of the femur which is attached to the head will disappear.

Fig. 1.

No. 3 in Fig. 1 shows a fracture which runs along the base of the neck where it merges with the trochanter mass and is known as the intertrochanteric fracture. It is partly intracapsular and partly extracapsular, as the capsule is attached anteriorly to the femur along the intertrochanteric line, whilst posteriorly its line of attachment runs about midway between the head and the trochanters. It is a common fracture and is often associated with a fracture in the trochanter mass, in which case its treatment is similar to that of the class of case to be next described. In its uncomplicated form its signs differ little from the variety just discussed except that the shortening is greater, about 1—1½ inches, and the treatment is the same.

In fracture of the neck of the femur, the head being fixed in the acetabulum, the displacement is always of the outer or limb fragment. If the separation is complete the displacement is usually upward, backward and outward, and to appose the fragment the limb must be lifted forward, rotated inward and drawn downward to its normal length. The normal abduction of the hip is limited by the contact of the great trochanter with the tissues above the acetabulum. When the limb is normally abducted the under part of the capsule is rendered taut and tends to retain the broken neck or head in normal relations, while the abducted position itself helps to force the broken neck more and more into its natural relations. In an impacted fracture the abducted position serves to reduce deformity without altogether separating the fragments and completely

on a level pelvis with all the landmarks corresponding, and the attitude in which the limb is fixed after adjustment of the fracture is one of complete abduction, complete extension and slight inward rotation. The body is then covered with flannel bandages reinforced by cotton wadding at pressure points and a plaster-of-Paris casing applied from the nipples to the toes of the affected side, a malleable iron bar being incorporated over the hip joint or several additional thicknesses of plaster to maintain the joint in complete extension. When the plaster is firmly set the patient is placed in bed and the head of the bed raised a foot or so by blocks. The opposite leg may be incorporated in the plaster by a spica extending down to the knee; this has the advantage of fixing the pelvis very firmly but restricts movement and so adds to the patient's discomfort. If

Fig. 2.

Fig. 3.

breaking up the impaction. In complete and unimpacted fractures the abducted position adjusts the fragments and fixes them. Figs. 2 and 3 illustrate the limitation of abduction caused by persisting deformity producing traumatic coxa vara, and the way in which forcible abduction restores the normal angle.

The patient having been anaesthetised, is placed upon an orthopaedic table provided with a pelvic rest and a perineal bar for counterpressure, but if these appliances are not available an ordinary table will serve. The limbs extended side by side are each supported by an assistant. Direct manual traction on the limbs is then made until the shortening has been reduced as demonstrated by comparative measurements. The injured limb is then rotated until the patella points slightly inward and the two assistants, still exerting equal traction on the limbs, then abduct them, that on the sound side slightly in advance, in order to demonstrate the normal range and to balance its fellow and prevent tilting of the pelvis. A final inspection shows the extended limbs equally abducted

the spica has been properly applied it is more comfortable than any traction apparatus which entails prolonged rest on the back. The plaster spica is retained eight to twelve weeks, a time sufficient to ensure adhesion of the fragments, but by no means a union capable of supporting the body weight. The patient after its removal remains in bed for two or three weeks longer for massage and passive and active movements, especial care being taken that abduction does not undergo limitation as is very liable to happen. A caliper walking splint is then fitted and the patient is allowed up. This splint must be worn until the X-ray shows perfect consolidation and full control of the limb has been restored.

In the young a separation of the upper epiphysis of the femur is comparatively common as a sequel of an injury, and is often overlooked for some months. A slight persistent limp leads to the discovery that the limb is shortened about half an inch and markedly adducted. A radiogram shows that the neck of the femur has been pushed

upwards and, is set at an angle of 100° or even 90° with the shaft, thus constituting one form of adolescent coxa vara. If recognised soon after the accident the treatment is to replace the neck in proper alignment with the head by forcible abduction and fixation in plaster-of-Paris. At a later stage when union in faulty position has occurred either a reconstruction of the fracture or subtrochanteric osteotomy will be required.

Cases occur where the abduction treatment has failed and non-union has resulted. These cases should be submitted to operation either by screwing or pegging the fracture if recent, or by Whitman's reconstruction operation if the non-union is of long standing. The description of this ingenious operation will be found in textbooks of orthopaedic surgery.

TREATMENT BY TRACTION.

Referring again to Fig. 1, the next site of fracture is that indicated as No. 4, the pertrochanteric fracture. The line of fracture

backward by its own weight and is pulled inwards by the adductors and upwards by the hamstrings. Thus the separation of fragments may be so great as to allow the interposition of a considerable bulk of muscle tissue which may lead to non-union. Whatever method of treatment be adopted, it is essential that the shaft of the bone be brought into line with the upper fragment by flexion and abduction.

In the middle third the fracture is more commonly oblique or spiral if due to indirect, transverse if due to direct violence. The overlapping and shortening is considerable and there is great tendency to angulation backwards or outwards, due to the action of gravity and the retraction of the adductor muscles. Reduction may be difficult owing to one or both of the sharp fragments being driven into the surrounding muscles. In the treatment of this fracture special care must be taken to sling the thigh in such a manner as to restore the natural anterior bowing of the femur. Fig. 4 shows how abduction in

Fig. 4.

passes through the trochanteric mass, comminution and impaction are commonly present, the neck of the femur being driven like a wedge into the trochanter splitting the latter into several fragments and separating off the lesser trochanter. This fracture is wholly extracapsular, there is $1\frac{1}{2}$ —2 ins. of shortening and the leg is strongly adducted and fully everted. There is an ample blood supply and there is no tendency to non-union in these fractures, but unless the shortening and adduction are corrected union takes place with very gross deformity.

Fracture No. 6 in Fig. 1 is the subtrochanteric fracture and lies in the upper third of the shaft of the femur. Its characteristic feature is that the upper fragment is tilted forward by the ilio-psoas muscle and abducted by the muscles attached to the great trochanter, whilst the lower fragment falls

this class of fracture may actually increase deformity. A careful study of the radiograph is essential for correct treatment and it is in these cases that a portable outfit, which will enable the position of the fragments to be checked after the extensions are applied, is so valuable.

In the lower third the dominating factor is the backward displacement of the lower fragment by the action of the gastrocnemius and the danger of pressure upon the vessels and nerves in the popliteal region. In oblique fractures the sharp pointed upper fragment may be driven into the quadriceps muscle. Unless the backward displacement is corrected it will lead to a condition of genu recurvatum when the patient begins to walk.

In all these fractures traction is the all important element in the treatment, combined with a varying degree of abduction in the

high fractures. Traction may be applied in two ways:—

(a) Fixed or passive traction is practically the same method as described above for first aid. After reduction under anæsthesia the limb is fixed in a straight 'Thomas' splint using a strapping or glued extension, the foot is held up at a right angle by a sole plate or some other form of support, and counter-fixation is secured by the back part of the ring fitting snugly against the tuber ischii. This method acts well in children, but in adults sufficient extension cannot be obtained without risk of slipping of the strapping, and the pressure of the splint against the tuber ischii is apt to cause soreness. This drawback may be obviated by employing the splint on the Hodgen principle, that is by raising the foot of the bed about six inches and utilising the patient's body weight to produce counter-traction. The Hodgen splint is bent at the knee and is suspended from a fixed point situated above and distal to the foot, the oblique suspension cords producing a long-axis traction against counter-fixation obtained by raising the foot of the bed. Neither of these methods are so efficient as:

(b) Active traction, which may be applied by adhesive strapping, by glued gauze, or by transfixion pins or calipers. Adhesive strapping, if fresh, holds well and is not irritating to the skin if a good brand of zinc oxide plaster be employed. Strips of gauze fastened by glue was a popular method during the war, but has not proved so successful in this country. Whether the reason lies in the quality of the glue or whether it be the heat and humidity which prevents it setting properly, it will be found that not only is the hold defective, but it is irritating to the skin. Pearson's modification of the Beasley caliper, which takes a grip of the condyles of the femur through two small incisions just above the condyles and is adjustable so that the points of the instrument do not penetrate the bone was very popular during the war in cases of compound fracture where extensive wounds rendered it difficult to use traction taking purchase from the surface of the limb. In the same class of case occurring in civil life it has a distinct though limited sphere of usefulness.

The limb having been fixed in the splint by strapping or glue, is slung and a weight is attached to the end of the splint by a cord running over a pulley, the foot of the bed being raised about 6 inches to provide counter-extension. The weight required for an adult is about 15 pounds or more, and herein lies the weak point of the method. Any form of extension except a caliper is bound to slip under the pull of these heavy weights, especially in this country where strapping does not hold as it does in temperate climates. As it gives way it usually takes some of the

epidermis with it, leaving an excoriated surface on which it is impossible to apply a fresh extension. One is then driven to employ an ankle, an unsatisfactory and dangerous method, or a Pearson caliper. All this can be avoided by employing a method which admits of efficient extension being obtained with a smaller weight. Such a method was described by Hamilton Russell of Melbourne in 1924(1) and the present writer, having adopted the method soon after it was published, is of opinion that the results obtained are superior to those yielded by any other method of treatment. It combines the method of active traction with the Hodgen principle, the weight required is light and no splints are employed. It is applicable to all fractures of the femur except the intracapsular group and those of the condyles. The principle involved is shown in Fig. 5 A. When the surgeon reduces a fracture of the femur he places one hand under the knee whilst the other grasps the leg above the ankle, the direction of the forces exerted by the surgeon's hands are shown by the arrows. By constructing a parallelogram of forces on them it will be seen that the resultant will be in the line of the thigh, the direction in which traction should be steadily exerted during process of repair.

Fig. 6 makes the arrangement of the apparatus clear. A Balkan frame is ideal, but it is possible to improvise this out of bamboo or other materials, the uprights at the head and foot being lashed to the frame of the bed. Four block pulleys which can be attached to the frame at various heights, and the ordinary materials for extension are the only other requirements. Usually an anæsthetic is not required for the application of the apparatus, unless the patient is restless and there is comminution of the fracture or much extravasation of blood. The leg having been prepared in the ordinary way is fitted with a "spreader" or stirrup close to the sole of the foot, attached to the leg by broad strapping strips carried up as far as the knee but not beyond it. A pulley is attached to the spreader by a bolt and nut. The extension strips should be firmly bandaged or the margins of the strapping may be split and carried up the limb in a spiral manner. Circular bands are dangerous unless great care is taken to apply them only at points where the limb is diminishing in circumference and to see that there is no pressure over the tendo achillis or immediately over the tibial tubercle. It is well to cut a hole in the strapping just below the head of the fibula to save the external popliteal nerve from all possibility of pressure. A broad sling—a folded towel answers admirably—is now passed beneath the knee, the ends of the sling are knotted together with a cord which is then passed through the pulleys on the following order—

(a) to a pulley placed on the horizontal bar in such position that a vertical dropped from it will meet the leg well below the knee; (b)

the spreader, and finally after passing through the lower pulley on the upright the cord is tied to a weight of about 8 lbs. for an average

Fig. 2.—The same 5 weeks later. No measurable shortening.

Fig. 3.—A pertrochanteric fracture with bad comminution. There is a great tendency to coxa vara in such cases.

Fig. 4.—The same 5 weeks later; except for some shortening of the neck caused by the impaction and tending to slight limitation of abduction, the result is satisfactory.

PLATE II.

Fig. 5.—A spiral fracture in the upper third. No abduction necessary in this case.

Fig. 6.—A spiral fracture in which moderate abduction was needed 5 weeks after the accident. No shortening and good alignment but some delay in union owing to separation of fragment.

Fig. 7.—A very bad type of fracture in the upper third with much shortening, wide separation and comminution. Likely to give a very bad result.

Fig. 8.—The same 7 weeks later. Insufficient abduction was employed, but there is only half an inch shortening, the alignment is good and the ultimated functional result will be excellent.

manner described and after slowly tightening up everything allows the weight to come into play. A soft pillow is now adjusted beneath the thigh to prevent gravitational sagging at the seat of fracture. Care must be taken that the heel does not touch the bed and a strip of strapping is attached to the sole and carried up to the horizontal bar to prevent foot drop. The foot of the bed should be raised 4 to 6 inches.

The arrangement described above provides that the pull on the leg is nominally double the upward lift at the knee, though actually somewhat modified by friction between cords and pulley. It will be observed that, contrary to the usual custom, the extension strapping does not pass above the knee. The supposed danger of straining the ligaments of the knee by taking extension through them is imaginary, since these ligaments are attached to a fragment of the femur and so cannot be stretched. Eversion gives no trouble as the slightly flexed knee is kept straight by the sling. If properly attended to the apparatus is very comfortable and readily permits of nursing. Constant supervision by the house surgeon is necessary, as the position of the patient relative to the line of traction is apt to vary, the pillow beneath the thigh may get displaced and so on. Fig. 5 B illustrates what may happen if the upward lift is too vertical, with the result that the traction will tend to increase that backward sagging of the femur which it is our principal object to prevent. The method is applicable to patients of all ages and to any fracture of the shaft. The amount of abduction can be varied at will by shifting the uprights so that the foot end of the Balkan frame is either inside or outside the legs of the bedstead. In Fig. 6, which represents the treatment of a fracture in the upper third, the Balkan frame is shown set for the abducted position. In middle and lower third fractures it would be within the legs of the bedstead.

The extension must be maintained for about five weeks on the average, by which time consolidation will be so far advanced that there will be no risk of late shortening developing. Needless to say this period varies considerably with the age and constitutional condition of the patient and the surgeon must be guided by what he finds at the seat of fracture and by the radiogram rather than by any set rules. The patient then lies in bed for another two weeks moving his limbs freely and being massaged daily. Meantime a walking caliper splint (2) is being made and when this has been fitted the patient is allowed up. The X-ray picture will show when it is safe to discard the walking caliper, usually about the end of the fourth month, but this will vary with the actual position of the ends of the bones; a slight lateral displacement with little or no shortening may delay

complete consolidation by a month or two. If a walking caliper cannot be fitted, the patient must be allowed up on crutches with the limb slung. After a time when a little weight can be borne sticks are substituted for the crutches and so on, but the risk of a fall and refracture during the early stages makes this method an anxious business.

The writer has been using this method for some four years and is entirely satisfied with it. Shortening is usually $\frac{1}{4}$ to $\frac{1}{2}$ inch, and in many cases there is none at all. The radiograms show that the bones have been brought into satisfactory apposition. It is rarely possible to obtain that exact anatomical reconstruction which follows a successful operation, but this is not necessary for function.

When a compound fracture is present, this method is more difficult to apply as the application of the dressings entails continual disturbance of the pillow under the thigh and therefore of the alignment. Fig. 7 illustrates the arrangement advocated for these cases. A Thomas' splint bent at the knee is fitted, extension strapping is applied to the limb and fastened to the end of the splint by tapes sewed on to the strapping. A weight of about 10 lbs. is attached to the end of the splint by a cord running over a pulley and the splint is slung in such a manner that there is a distinct forward as well as upward pull, as in the Hodgen method. Very satisfactory extension can be thus maintained and the wound is easily reached for dressing by opening the slings which consist of broad bands of flannel attached to the side bars of the splints. A reservoir for Dakin's solution for the Carrell-Dakin treatment can be suspended from the bar of the Balkan frame.

In subtrochanteric and high upper third fractures very considerable abduction will be required to bring the lower fragment into correct alignment. In such cases a radiogram should be taken early in the course of treatment. If the result shows the fragments to be in a position such as those in Plate II, Fig. 7 the patient should be anaesthetised and an endeavour made to manipulate the fragments into better apposition; whether this is successful or not the limb should then be put up widely abducted in a straight Thomas' splint with the usual weight extension. In such cases the fragments will often be found to be united only by soft callus after seven or eight weeks, owing to the separation of the fractured ends. A few weeks fixation in a plaster-of-Paris spica will usually result in sufficient consolidation for a caliper splint to be fitted, which should be used until the radiogram shows firm ossification, usually six months or more from the date of the accident. Patience is essential with these cases, but if sound orthopaedic methods are employed, the results are generally functionally satisfactory,

though not anatomically so pleasing as those obtained by operation. Plate II, Fig. 8 shows a consolidating fracture in which measures to abduct the lower fragment were not taken sufficiently early. There is considerable separation and union is delayed, but the alignment is good and there is barely half an inch of shortening, the functional result promises to be just as good as could have been obtained by operation.

Very few cases will require operation if the above lines of treatment are carried out. Occasionally it happens that a sharp end of bone perforates muscle with the result that

or malunion, and these constitute a problem in orthopædics which is outside the scope of this paper.

Fractures of the condyles and separation of the lower epiphysis are intra-articular lesions requiring quite different treatment. By manipulation under anæsthesia the fragments are got into good position, and the joint is maintained in flexion until a walking caliper can be fitted. Most of these cases however call for open operation and usually result in an ankylosed knee joint. If this is inevitable the surgeon should see that it takes place in full extension.

Fig. 7.

the shortening can only be reduced by the exercise of considerable force and then recurs as soon as the pull is released with a feeling of elastic recoil which is quite characteristic. A lump can usually be felt caused by the projection outwards of one of the fractured ends, and operation in these cases is imperative. The fragments should be cleared of interposed muscle tissue, and fixed or not as may be judged necessary. If fixation is employed, Parham's hands are best for these oblique sharp-pointed fragments which are difficult to fix by Lane's plates. The only other cases requiring operation are those where other lines of treatment have led to failure of union

My best thanks are due to Rai Dr. Lal Behari Ganguly Bahadur, Teacher of Medicine, Campbell Medical School, for the excellent radiographs with which this paper is illustrated and to Sub-Assistant Surgeon Dr. Surendra Nath Moitra, Resident Medical Officer of my ward, to whose interest and careful supervision the excellent results obtained are largely due.

ARTIFICIAL PNEUMOTHORAX TREATMENT IN INDIA.

AN ANALYSIS OF 306 CASES.

By C. FRIMODT-MOLLER, M.B., Ch.B. (Copenhagen),

Medical Superintendent, Union Mission Tuberculosis Sanatorium, Arogyavaram, near Madanapalle, South India.

For many reasons in India it is almost impossible to keep more than a few patients under artificial pneumothorax treatment longer than one or two years. In the West the refills are usually continued for three to four years, and in many cases even for several years more. The question is, therefore, is it worth while under Indian conditions to begin what R. C. Wingfield of Brompton Hospital Sanatorium has described(1) as "the most important advance that has been made in the treatment of tuberculosis in recent years"? This is the question considered in this paper.

HISTORICAL REMARKS.

The introduction of artificial pneumothorax treatment into India was made comparatively few years ago. In Europe it is now more than forty-five years (1882) since the Italian doctor, Forlanini, began to experiment with insufflation of air into the pleural cavity as a treatment against pulmonary tuberculosis. His results were published in 1895, and following him other doctors on the Continent began to investigate the value of this new method. In 1907 Saugman of Denmark put the treatment on a really scientific basis by introducing the water-manometer as the indicator for determining the presence or not of the needle in the pleural cavity, and for judging the amount of air to be insufflated.(2) The introduction of the manometer made the whole pneumothorax treatment safer and more perfect.

Four years after this improvement the treatment was employed in England for the first time, but for several years it was used and advocated by only a few specialists. Lately, however, it has gained much ground as can be seen from recent literature.

THE PRINCIPLES OF THE TREATMENT.

The principles are exceedingly simple. By the insufflation of air into the pleural cavity the diseased lung is collapsed and thereby immobilized. The effect of the collapse is that the toxins contained in the lesions in the lung are, so to speak, squeezed out of it like water out of a sponge. The sudden inflow of toxin into the circulation produced by the collapse is often the cause of a sharp rise of temperature on the day of insufflation. After these toxins have been neutralised or excreted the temperature falls again. Any fever present previous to the treatment may soon totally disappear, as the immobilization following the collapse prevents new toxins being produced and circulated to the same extent as before, because of the reduced size of the collapsed lung and of any cavities present, and

specially because of the stasis created in the lymphatic vessels by the pressure. Further, the blood stasis also produced by the immobilization is beneficial to the natural healing process of formation of fibrotic tissue and scars. The treatment practically puts the diseased lung out of function and so prevents it from having an adverse influence on the whole body. In this way, theoretically, artificial pneumothorax treatment is an ideal measure, and fortunately it often is so in reality, giving the most strikingly good results.

Nevertheless, in many cases, pneumothorax treatment does not produce a satisfactory result. This is no cause for discouragement of the use of the treatment and it is not surprising, when we take into consideration both the serious nature of the disease, the degree of activity present in such cases, the extent of the lesions, the condition of the contralateral lung which is often affected as well, and the presence of complications. The ultimate good results depend also upon whether a complete or partial collapse is obtained, and this depends again upon absence or presence of adhesions in the pleural cavity.

From this it will be understood that the treatment is only to be used in selected cases and with great reservation as to the results to be obtained, because a marked initial improvement often changes during the course of refills to a condition which is little different from that previous to the treatment. Such a possibility should always be kept in mind when this treatment is suggested to a patient.

With this reservation it can be said that pneumothorax treatment has proved to be a remarkable one. Large statistics regarding the after-results of it are now available for judging its real value. There is a wonderful agreement as to the results obtained. The value of the treatment can best be expressed in the words of C. Matson and his colleagues(3) that it is conservative to estimate that the treatment will restore to health 40 to 50 per cent. of the cases having forms of chronic and acute phthisis of whom, otherwise, not over 7 per cent. would recover.

THE RESULTS IN INDIA.

During the last seven years at Arogyavaram we have treated with artificial pneumothorax 306 patients.

In 90 out of this number it was not possible to find free pleural space. This proportion of patients with adhesions in the pleural cavity corresponds to what is usually found elsewhere, namely one in three or one in four. These patients originally selected for pneumothorax treatment and not receiving it, serve as controls in our investigation, because they have all been treated in the sanatorium under exactly the same conditions as those to whom the treatment could be given.

From the following tables it will be seen that we have given the treatment chiefly to patients in the very advanced stage of the disease. No real improvement can therefore be expected in

these patients unless they have been at least half a year under treatment. This has been impossible in a great number of cases, and the pneumothorax treatment has had to be discontinued for purely medical reasons, such as the presence of or the formation of adhesions, the contralateral lung not being able to stand the strain of the whole work of respiration, and tubercular or other complications.

In order to do justice to the real value of the treatment we have therefore divided our patients into two groups, those who have had the treatment for less than half a year, and those who have had it for more, as shown in Table I.

TABLE I.

Duration of Artificial Pneumothorax Treatment of 216 Patients.

Duration of Treatment with Artificial Pneumothorax at the Sanatorium.	Number of Cases.
Less than six months	124
More than six months	44
" " 1 year	42
" " 2 years	6
" " 3 years	0

It will be seen that of 216 patients in whom air was introduced, in 124 the treatment lasted less than six months; indeed in some not more than a few days. In 92 patients it continued longer; in 6 only more than 2 years, 42 between one and two years, in 44 between six months and one year. Compared with the duration of treatment in the West our patients have been treated for a comparatively very short time.

The result of treatment of the 216 patients together with the 90 controls is shown in Table II.

TABLE II.

Result of Treatment of 216 Patients, with 90 Controls.

	Number of Cases.	Stage.	Died during 1921 to 1928.	Unknown in 1928.	Living, but not able to work in 1928.	Living, but clinically well and able to work in 1928.
Treated with artificial pneumothorax more than six months.	92	{ II, 10% III, 90%	30=32·8%	8=8·7%	13=14·0%	41=44·5%
Treated with artificial pneumothorax less than six months.	124	{ II, 7% III, 93%	52=41·9%	36=29·0%	27=21·9%	9=7·0%
Controls. Pneumothorax attempted, but no air insufflated.	90	{ II, 5% III, 95%	47=52·2%	12=13·3%	22=24·4%	9=10·0%

By the term "clinically well and able to work" is understood that the patient has become free from the clinical symptoms of the disease, that

he has no fever even after work and exercise—that the cough and sputum have ceased or almost ceased, that he has gained considerably in weight, and that he feels perfectly well in all respects. In 25 per cent. of these patients tubercle bacilli are still to be found in the sputum (75 per cent. have lost the bacilli), and in a number some signs of disease are still to be heard in the lungs, although from a clinical point of view the disease has become inactive.

From the table it will be seen that in each of the three groups 90 per cent. or more of the patients were in the III stage and that no patient was in the I stage. Of these patients 44·5 per cent. are "clinically well and able to work" from amongst those who have had the treatment more than 6 months, compared with only 7 per cent. of those having had it less than 6 months, and 10 per cent. of the controls.

It is possible that, if we knew the after-history of those whose present condition is unknown, the percentages in the different groups might be changed, but it would not be to an extent sufficient to affect the main results. The fact that about 32 per cent. of those treated longer than six months (*see* Table II) are known to have died during the years under review is a strong warning against being over-enthusiastic about the value of the treatment. The percentage of deaths is approximately that found all over the world. On the other hand the fact that 44·5 per cent. are clinically well and able to work is certainly encouraging when compared with the low percentages of the other groups. The pneumothorax treatment even brings those III stage patients who have been treated more than half a year and who have had a complete pneumothorax prognostically into line with the I and II stage patients. From Table III it will be seen that of this group of III stage patients 58 per cent. are clinically well and able to work; this figure is close to that of 66 per cent. being the percentage of 534 patients in

the I and II stages treated in the sanatorium during the same seven years, who are now alive and able to work, namely 352.

PLATE I.
Types of Artificial Pneumothorax.
(Photos by U. M. T. SANATORIUM).

Fig. 1.—Complete pneumothorax in right side. Lung seen as shadow at hilus.—Result: clinically well. Treatment continued.

Fig. 2.—Partial pneumothorax in left side. Strong adhesion. Result: clinically well; still under treatment.

Fig. 3.—Old fibrotic tuberculosis of right lung. Heart pulled over to right side.

Fig. 4.—Same patient as in fig. 3. after pneumothorax.—Adhesions upper part preventing complete collapse. Heart pushed back. Result: greatly improved; still under treatment.

PLATE II.
Types of Artificial Pneumothorax.
 (Photos by U. M. T. SANATORIUM).

Fig. 5.—Partial pneumothorax in left side. Small adhesion at apex; effusion. Result: improved; still under treatment.

Fig. 6.—Old fibrotic tuberculosis in left lung. pneumothorax tried in vain, no free pleural space.

Fig. 7.—Severe tuberculosis in right lung. Female patient.

Fig. 8.—Same patient as in fig. 7, after pneumothorax.—Almost complete collapse. Result: greatly improved; still under treatment.

TABLE III.
Difference in Result of Complete and Partial Pneumothorax.

	Number of Cases.	Clinically well and able to work.
Complete pneumothorax	57	33 = 58 per cent.
Partial pneumothorax ..	35	8 = 23 per cent.

The prognosis for the patients with only a partial collapse is here seen to be much less hopeful, for of 35 of these patients only 8, or 23 per cent. are clinically well.

The condition of the patients in relation to the time since pneumothorax treatment was begun, without reference to the duration of this treatment, is shown in Table IV. It should be kept in mind (as seen in Table I) that none of these patients have had the treatment for three years, and only six more than two years, while the great majority of those who became well had it for less than two.

TABLE IV.
After-results of Treatment of 216 Patients.

Time from beginning of artificial pneumothorax without reference to duration of this treatment.	Died during 1921 to 1928.	Unknown in 1928.	Living but not able to work in 1928.	Living but clinically well and able to work in 1928.
Less than six months ..	27	..	23	3
More than six months ..	19	4	6	6
" " 1 year ..	22	13	6	17
" " 2 years ..	7	5	3	10
" " 3 years ..	4	3	..	4
" " 4 years ..	1	2
" " 5 years	3	2	4
" " 6 years ..	2	13	..	6
" " 7 years	1
Total cases : 216 ..	82	44	40	50

From a study of the table it will be seen that in spite of the comparatively short period of treatment a considerable number of the patients were clinically well and able to work years after the treatment was begun, and that quite a few are known to be in a clinically healthy condition, living a normal life, even up to six years later, that is, at least three years after the pneumothorax treatment had stopped. In this connection it is worth while to mention that E. Rist records 51

cases among his patients who were under treatment for only a comparatively short time, "who turned out quite surprisingly well, as if the process of healing initiated by a temporary collapse went on despite its interruption." (4)

THE INFLUENCE OF EFFUSION IN THE PLEURAL CAVITY.

The question of appearance of effusion in the pleural cavity during the course of pneumothorax treatment and its influence on the ultimate results has been much discussed. Some observers consider this complication detrimental to the best progress of the patient, while others with equally great authority consider fluid without any such influence. The percentage of patients showing fluid varies very much in the different statistics, most of the observers recording 40 to 50 per cent. of patients with effusion, while a few have a smaller number and others higher, even as high a number as 75 per cent. We have among our 216 patients had effusion in 43.5 per cent. Of the patients recorded as clinically well 42.4 per cent. have had pleural effusion. This number being practically identical with that for all our patients treated supports the view that effusion is of little consequence for the ultimate result.

In those cases where the clinical symptoms indicated aspiration of the fluid, we have never observed any empyema, by microscopical or cultural examination of the fluid. The aspiration has always been made with simultaneous insufflation of air which makes the operation without discomfort to the patient. The chief objection to effusion is the great risk of adhesions being formed below the fluid and the collapse thereby being reduced in efficiency.

THE DANGER OF PNEUMOTHORAX TREATMENT.

The danger of pneumothorax operation is not to be considered too lightly, although the present improved technique has much reduced it. The number of sudden deaths during the operation is in the West considered to be 1 in 1,000 to 1 in 1,500 of operations, (5) including the refills where after all the most accidents happen. (6) There is still much difference of opinion regarding the cause of the sudden deaths whether they are due to air-embolism or to pleural shock, a nervous reaction to the penetration of the pleura. This question has not been solved yet. That air-embolism can occur without air being let in from the apparatus is proved by the finding of air-emboli post-mortem in some cases where no air was given before the accident occurred. The explanation is that the needle has penetrated a vein in the lung and this vein being kept rigidly open by surrounding inflammatory tissue does not close, but because of its natural negative pressure sucks in air from the lung alveoli, or from the air already in the pleural cavity from previous insufflation. By following strictly the detailed and improved technique of Saugman, which we have had the privilege of learning from himself, we have up till now seen alarming symptoms in only two cases out of almost 4,000 insufflations

including the refills, and these patients quickly recovered. The other recorded unfortunate symptoms of convulsions, hemiplegia, and paralysis we have never observed. We conclude with Lillingston(7) that the only effective "treatment" of these unfortunate complications is of course the prophylaxis, which consists in a meticulous attention to the details of technique.

THE AMOUNT OF PRESSURE.

The amount of air injected is usually for the first insufflation 300 c.c. if this amount will allow the pressure in the pleural cavity still to be negative. Otherwise a smaller amount is given. The next refill is given the following day and after that time one day is added to the interval between the refills. The great controversy which existed during the first years of artificial pneumothorax treatment as to whether the collapse should be made with as large refills as possible even up to 1,500 c.c. or more, leaving a positive pressure in the pleural cavity, has now practically ceased. Most workers now use smaller refills and attempt to induce a complete collapse under as low a pressure as possible.

THE SEDIMENTATION TEST AS A GUIDE.

We have a modern guide to judge the efficiency of the produced collapse in the sedimentation test. It is not possible here to go into details regarding the value of this test in the treatment with artificial pneumothorax. Those who would like further information on this question with regard to Indian patients are referred to an article by us in "Tubercle." (8) It will suffice here to mention that further research with the test in 66 cases in whom the sedimentation test was made before and after treatment with artificial pneumothorax confirms the figures, giving the percentage of the fall of the red blood corpuscles as decreasing rapidly, sometimes even to normal, in cases of complete collapse. Absence of such fall indicates a partial collapse or the appearance of active lesions in the contralateral lung or other complications interfering with the good progress of the patient.

SUMMARY.

1. 306 patients have been treated with artificial pneumothorax of whom more than 90 per cent. were very advanced cases. In 90 adhesions totally prevented insufflation of air and of these 10 per cent. became clinically well.

124 patients were treated with artificial pneumothorax less than six months and of these only 7 per cent. became clinically well.

92 patients were treated more than six months and of these 44.5 per cent. became clinically well and able to work.

2. Of the 92 patients treated for more than six months 35 had a partial pneumothorax and 57 a complete. Of these 57 patients 58 per cent. became clinically well, a percentage closely approximating to the figures for the I and II stage patients who have had no need of pneumothorax.

Of the patients with partial pneumothorax only 23 per cent. are clinically well.

3. The duration of the treatment was in no case more than 3 years, and in only 6 cases over 2 years, yet a number of such patients are living and working even six years after treatment was begun.

4. In almost 4,000 insufflations no sudden deaths occurred during the operation. Two patients only showed passing alarming symptoms. No patients showed distressing complications as reported by other workers.

5. Effusion appeared in 43.5 per cent. of the cases in which air was insufflated, but this complication seems to be of little consequence as regards prognosis.

6. Although in India it will be a long time before patients in any number will be able to continue artificial pneumothorax treatment after leaving the institution in which it was begun, yet a shorter treatment is of value, for we find that of those patients who receive from six months to two years treatment with pneumothorax, 44.5 per cent. are well and able to work, while of similar patients not treated with pneumothorax only from 7 to 10 per cent. obtain equal results.

STOCK SOLUTIONS OF QUININE.

By J. W. D. MEGAW, C.I.E.,
LIEUT.-COL., I.M.S.,

SUDHAMOY GHOSH, D.Sc.,

Professor of Chemistry, Calcutta School of Tropical Medicine,
and

N. R. CHATTERJEE, M.Sc.,

Calcutta School of Tropical Medicine.

Reasons why Quinine often fails:—In the *Indian Medical Gazette* of January 1907, the senior writer called attention to the frequency with which patients failed to receive the doses of

quinine which were prescribed for them. Two reasons were given, (1) the patients themselves often object to the drug and fail to take it, although they may pretend that they are doing so; (2) stock mixtures in dispensaries are often under the stated strength and fraudulent misappropriation of quinine has to be guarded against.

Many other medical men have repeatedly pointed out the fallacies connected with quinine administration but yet the two-fold fraud continues, fraud on the part of the patients and fraud or carelessness on the part of compounders.

Many observations on the clinical action of quinine are utterly vitiated because the investigators have assumed that writing a prescription or giving an order constitute evidence of the administration of the stated amounts of quinine. The truth is that we have no assurance that quinine has been taken unless we have actually seen the mixture made up and administered. When strict precautions are taken "quinine resistance" becomes so rare as to be almost negligible.

This note has been prepared with a view to discovering to what extent variations occur in

the solutions of quinine or cinchona febrifuge. The quantitative estimations were carried out by taking a known volume of the mixture, making it alkaline with ammonia or caustic soda, and extracting the alkaloid with a mixture of chloroform and ether. The residual alkaloid was dried to a constant weight and the weight of the salt calculated from the base thus obtained. The results which appeared abnormal were always checked by duplicate analyses.

The dispensaries from which the stock solutions were taken are not likely to be worse than the average; they were under the charge of medical men who readily agreed to co-operate in carrying out the tests, whereas several other medical men who were approached showed a decided reluctance to help in the enquiry.

The samples were taken without previous notice having been given, but it is possible that some of the dispensaries may have been on their guard owing to having received information that samples had been taken from other dispensaries in the neighbourhood.

TABLE I.

Showing the Prescribed Strengths of the Stock Solutions and the Actual Strengths as found by Accurate Quantitative Analysis.

No.	Nature of the mixture.	Quantity of alkaloid according to the prescription in grains.	Actual quantity found by analysis.	Source.

90	Cinchona febrifuge mixture	12	12.43	Ditto.

TABLE II.

Showing the Stated Amount of Quinine and the Actual Amount found in Tablets.

No.	Tablets.	Quantity of alkaloid per tablet in grains.	Actual quantity found by analysis.	Source.
1	Quinine tablets	4	3.49	Post Office 1.
2	Quinine tablets	4	3.54	Do. 2.
3	Quinine tablets	4	3.53	Do. 3.
4	Quinine tablets	4	3.64	Tea Estate.
5	Quinine tablets	2	2.044	Private Manufacturer.

Comment.—Of 90 stock solutions, no less than 23 or 25.5 per cent. were 25 per cent. or more weaker than the stated strength, while 9 of these were 50 per cent. or more below the stated strength. If deficiencies of 10 per cent. or more are regarded as significant, it is found that 40 per cent. of the solutions are deficient. Eleven were 25 per cent. or more above the stated strength, two of these showing 50 per cent. or more of excess in the alkaloidal content.

Slight variations may well be ignored, but it is rather disquieting to find that a patient may be ordered ten grains of quinine and may receive only four to seven grains, even if the full quantity of stock solution is actually given and swallowed by the patient. It would be unsafe to assume that a deficiency in the stock solution is the only fallacy with quinine administration, it is just as easy to give short measure in making up the prescription as to give short weight in making up the solution.

When quinine is given as a "mass treatment" (the so-called "prophylactic" administration) there are even greater possibilities of fraud and error, and when we find that the stock solutions of the most carefully supervised dispensaries are liable to be much below the stated strength it becomes clear that the amount of quinine which is stated on the prescription bears no necessary relationship to the amount which is actually swallowed.

Method of Checking the Strength of Stock Solutions of Quinine.—Dr. O. E. McCutcheon, one of the medical men who kindly co-operated in supplying solutions for examination, enquired whether there was any rough and ready test by which the medical man could check the dispensary solutions. His enquiry stimulated the senior writer to request Dr. Ghosh and Mr. Chatterjee to work out a rough test by which it would be possible to detect any considerable variations in the strength of stock mixtures. The following test may be adopted.

Requirements:—1. A supply of long narrow test tubes of equal calibre (5 to 7 mm. diameter if possible). Wider tubes may be used but they would necessitate the use of larger amounts of the solutions. Calibrated and graduated tubes such as centrifuge tubes, are preferable if available.

2. *Reagent:*—Dissolve 20 grams of Merck's pure phosphotungstic acid in 100 c.c. of 12.5 per cent. sulphuric acid. (The dilute H_2SO_4 is made by adding 5 c.c. of B. P. concentrated sulphuric acid of 1.84 specific gravity to 50 c.c. water, cooling, and making up to 70 c.c. with more water.) It is well-known that water should not be poured into the strong sulphuric acid.

3. The stock solution which is to be tested. (This should be diluted if it contains more than 20 grains of the alkaloid in each ounce; in this case, the control solution will be diluted in the same proportion.)

4. A freshly prepared solution should be made up in one's presence, using the same amount of

quinine or cinchona febrifuge as is supposed to be present in the stock solution, the powders which are in stock in the dispensaries being employed.

5. In cases of doubt as to the purity of the powdered alkaloid in stock, another solution should be made using powders of known purity. This will serve as a control of the quality of the stock powders.

Method:—In one tube take one c.c. (or one part) of the stock solution, in another tube take exactly the same amount of the freshly prepared solution (a third tube may be used for the solution made from alkaloids of known purity). Measurement by a pipette is desirable but with reasonable care equal quantities can be measured.

To each of the tubes add 2 c.c. (or 2 parts) of the reagent and 1 c.c. (or 1 part) of water. Mix thoroughly by rolling the tubes between the hands for about a minute keeping them in a vertical position. Do not stir or shake the solutions. Allow the precipitates to settle for 2 or 3 hours and compare their heights. Any great variations will indicate the necessity for an accurate quantitative examination of the stock mixture.

If centrifuge tubes and a centrifuge are available the examination can be completed in a few minutes, but the test has been specially worked out so that it can easily be carried out with the simplest possible equipment.

The test solution ready made up can be obtained from any reliable chemist by supplying him with the formula. It keeps indefinitely. It is essential that the tubes employed should be of equal calibre and the quantity of the quinine solution in each tube must be the same. The total volume should be such as to give a 5 per cent. solution of sulphuric acid, at which the reagent acts best.

No claim of great accuracy is made for this test, but it will be found useful as a rough check of the strength of dispensary solutions. As already stated, it can also be used to detect any serious deficiencies in the purity of the powders from which the stock mixtures are made.

If all the stock mixtures which are dealt with are made up according to one or two known prescriptions, time will be saved by using these as controls instead of making up fresh solutions from the dispensary powders; but in this case there are possible fallacies to be considered, and it is desirable to carry out the test under conditions which do not admit of the introduction of errors due to the presence of unknown factors.

THE TREATMENT OF PERNICIOUS ANÆMIA BY LIVER.

By J. B. VAIDYA,

MAJOR, I.M.S.,

District Medical Officer, Guntur.

THE publication of several papers in the journals on the treatment of pernicious anæmia by liver tempts me to record the results obtained with this line of treatment in this hospital. The

treatment by liver was started in July 1927, as a result of the publication of reports of the liver treatment by Minot in the *British Medical Journal*.

The treatment adopted in these cases is as follows:—

1. Dilute hydrochloric acid up to $1\frac{1}{2}$ drachms diluted with water to be taken during and after meals.
2. Iron and arsenic by the mouth.
3. Injections of "Hæmoplas" once a week.
4. Liver extract ($1\frac{1}{2}$ lb. of sheep's liver) daily.
5. Anthelmintics in some cases, specially for hookworm.

The cases treated were almost all females with anæmia and pregnancy. Blood counts were made and if there was marked anisocytosis with tendency to megalocytes and high colour index with or without nucleated cells, they were classed as pernicious anæmia. Generally, nucleated red blood cells were found in these cases. The majority of them had glossitis at one time or other, and in some cases the lemon yellow tint was very marked.

There was marked improvement in all cases except two. The patient's blood count and general health improved very much and they had a good colour before leaving the hospital.

Out of 57 cases of pregnancy complicated with anæmia admitted here from July 1927 to the end of December 1927, 13 were of pernicious anæmia type. Unfortunately, the complete records of all these cases are not available.

Pernicious Anæmia following Sprue.—A medical student from Bombay was admitted to this hospital for anæmia. He had bilateral parotitis, stomatitis, and then developed a typical attack of sprue in November 1927 and was treated in Bombay for this complaint. Gradually he developed anæmia, and when I saw him he had a lemon yellow tint, glossitis, and intense anæmia. The blood showed marked anisocytosis, poikilocytosis; megalocytes were present and showed a tendency to preponderance. A few nucleated red blood cells were present. The colour index was high. There was glossitis. He was also complaining of offensive stools which were rather bulky at times. He was put on the general treatment which is being adopted in this hospital for pernicious anæmia, viz., dilute hydrochloric acid, liver extract, iron and arsenic, and hæmoplas injections. In addition, he was given calcium and parathyroid by the mouth for his sprue.

The blood counts were as under:—

Blood on 8th January, 1928, showed anisocytosis, poikilocytosis, nucleated red cells, with megalocytes present.

Red blood cells 1,500,000.	Hæmoglobin 40%
Colour Index 1.3	White blood cells.
	Polymorphocytes 65%
	Lymphocytes 32%
	Eosinophiles 2%
	Transitionals 1%

1st February, 1928.—Colour Index 1.25. Hæmoglobin 70 per cent. Red blood cells 28,000,000. Nucleated cells were not seen.

22nd February, 1928.—Colour Index 1.3. Hæmoglobin 90 per cent. Red blood cells 3,500,000. No nucleated red cells were seen.

11th March, 1928.

Red blood cells	.. 3,481,500
White blood cells	.. 6,500
Hæmoglobin	.. 85 per cent.
Colour Index	.. 1.25

Anisocytosis, Poikilocytes, very few; no nucleated red cells.

Weight 106 lbs., colour, good.

25th March, 1928.

Red blood cells	.. 4,550,000
White blood cells	.. 4,375
Hæmoglobin	.. 90 per cent.
Colour Index	.. 1.0

Anisocytosis, not marked. Poikilocytes, very few. No nucleated red cells.

Weight 109 lbs.

Hæmoplas injections were stopped on 22nd February, 1928, and the patient was getting liver extract; dilute hydrochloric acid and iron and arsenic mixture.

He developed glossitis while under treatment. It disappeared in about a week. When the patient left the hospital, he was much improved and had a good colour. He is still under treatment as an outpatient and is under observation.

The sequence of sprue followed by anæmia of a pernicious type was met with in some cases seen in Devalali, a cantonment station about 130 miles from Bombay. All the cases seem to have commenced their illness while in Bombay. In the majority of cases the symptoms started with gastro-intestinal disturbances resembling sprue. Some of these cases occurred in men who led a very active healthy life but who had to stay in Bombay for a few months by turns, coming back to Devalali on completion of their tour of duty.

Invariably they attributed the onset of disease to their stay in Bombay, where they first noticed their illness. I have not got any notes about these cases, but I remember the case of one lady, who was living in Bombay and who was ordered a change to Devalali for the benefit of her health. In the beginning she had sprue, followed later on by intense anæmia. Her blood count, as far as I can remember now, showed a high colour index. There were poikilocytosis, megalocytes and a few nucleated red blood cells. She was put on dilute hydrochloric acid with Hæmoplas injections; whey and yeast and arsenic by the mouth. When last, I saw her, the colour index had gone below 1, and her general health had improved very much.

The reason for employing Hæmoplas was that Hæmoplas is said to be a suspension or extract of "sanguine globules" (red blood cells).

Though I do not remember correctly, I think it was Lawrence, who about three or four years back published a paper in the *British Medical Journal* showing that the injections of the substance he prepared from the blood of an ox—red blood cells?—induced a higher blood count. Hæmoplas, a preparation by the Anglo-French Drug Company, was on the market and was said to contain sheep's corpuscles in suspension. It was therefore thought in view of Lawrence's work that the injection of this preparation would be beneficial, and the results obtained have been very encouraging.

In the *British Medical Journal* of February 4th, 1928, in the article on treatment of pernicious

anaemia with liver by Dr. Brewer and Fraser, it is remarked that:—"The similarity of pernicious anaemia in many of its symptoms and signs to pellagra, sprue or beri-beri, suggested that, like these diseases, pernicious anaemia might be associated with a faulty diet."

The onset of anaemia in these cases after a sprue-like disorder is of interest. Further, in the case of the medical student, the attack of bilateral parotitis (? mumps) might suggest septic infection as being one of the causes which may have caused anaemia of the pernicious type, since it is considered that septic poisoning and absorption play some part in the causation of anaemia of this type.

*PLASMOCHIN AS COMPARED TO QUININE IN THE TREATMENT OF MALARIA.

By P. V. KARAMCHANDANI,

CAPTAIN, I.M.S.,

In-Charge Indian Military Hospital, Pishin.

In the August 1927 issue of the *Indian Medical Gazette*, the place of Plasmochin in the treatment of malaria has been ably discussed. Some ground has however been left uncovered, and I propose to supplement the above article by giving the results of my independent clinical investigations,

(4) and intractable cases that fail to respond to quinine.

It is an admitted fact that quinine causes leucopenia. In pneumonia however leucopenia is the very thing to be avoided, in fact the present-day treatment of pneumonia is centering round leucocytosis. Thus the practitioner is confronted with a problem, not easy of solution, when his patient develops pneumonia complicated with malaria. In India, where malaria is so prevalent, and a concurrent pneumonia not uncommon, the question assumes special importance. The opinions of doctors differ with regard to the administration of quinine in pneumonia. Some from fear of leucopenia avoid quinine altogether. Some on the other hand give full doses, considering the cure of malaria more important, while others work between these two extremes. This can scarcely be regarded as a satisfactory state of affairs. I therefore tried to see if one could come to a conclusion on the subject after careful observation of the results of the working of drugs tried for malaria.

I selected two cases of lobar pneumonia complicated with benign tertian malaria. I took their leucocyte count and put one on Plasmochin and the other on quinine. After three days' treatment I took their count with the following results:—

Name.	Disease.	W. B. C. count before treatment.	Treatment.	Result after 3 days' treatment.
Hakimali	Pneumonia with benign tertian malaria.	6,250 per c.cm.	Quinine sulph. gr. xx per day. 2 injections of sodium nucleinate.	W. B. C. 5,500 <i>P. vivax</i> present.
Bilawar	do	6,500 per c. cm.	Plasmochin 0.06 gm. per day. 2 injections of sodium nucleinate.	W. B. C. 11,000; no <i>P. vivax</i> .

with a view to showing the effect of Plasmochin on:—

- (1) the white blood corpuscles,
- (2) gravid uterus,
- (3) patients who have an idiosyncrasy for quinine,

Then I selected two cases of malaria, both with very heavy infection, one with *P. vivax* and the other with *P. falciparum* and put the former on Plasmochin and the latter on Plasmochin Co. (tablet 1 t.i.d.). Their total counts were taken before the treatment was started and then daily during treatment, with the following results:—

Name.	Day of treatment.	Treatment received (Total).	Species of parasites.	W. B. C. count.
Mushtakhan	Nil.	<i>P. vivax</i> +++ <i>P. falciparum</i> few.	6,875 per c.mm.
	First	0.06 gms. Plasmochin.	<i>P. vivax</i> and <i>P. falciparum</i> equal.	6,625 " "
	Second	0.12 gms. Plasmochin.	<i>P. vivax</i> few. <i>P. falciparum</i> more prominent.	6,562 " "
	Third	0.18 gms. Plasmochin.	<i>P. vivax</i> nil. <i>P. falciparum</i> present.	7,125 " "
	Fourth	0.24 gms. Plasmochin.	<i>P. vivax</i> nil. <i>P. falciparum</i> present.	7,500 " "

Name	Day of treatment.	Treatment received (Total).	Species of parasites.	W. B. C. count.
Maniram ..	Fifth ..	0.24 gms. Plasmochin & Plasmochin Co. 3 tablets.	No parasites seen ..	7,187 per c.mm.
	Sixth ..	Plasmochin 0.24 gms. & Co. 3 tablets. Quinine sulph. gr. 40 orally	No parasites seen ..	4,375 „ „
	First	Nil.	<i>P. falciparum</i> ..	6,562 „ „
	Second ..	Plasmochin Co. 3 tablets.	<i>P. falciparum</i> disinintegrating.	6,093 „ „
	Third ..	Plasmochin Co. 6 tablets.	<i>P. falciparum</i> very few.	6,875 „ „
	Fourth ..	Plasmochin Co. 9 tablets.	No parasites seen ..	6,562 „ „
	Fourth ..	Plasmochin Co. 9 tablets and quinine gr. 40 orally.	No parasites seen ..	4,781 „ „

As sodium nucleinate injections raise the leucocyte count in pneumonia they were given in the first two cases quoted above. The result as shown above, was a good rise in the second case in which the action of the drug does not seem to have been counteracted by Plasmochin which was also administered with it; where as the rise in the first case was only slight, due perhaps to the drug having been counteracted by the leucopenic effect of quinine, although it is possible that this may even be due to the individual case. In the two cases of malaria referred to above, Plasmochin appears to have definitely prevented leucopenia.

Further, in all these cases in which Plasmochin was used, no cyanosis or any other untoward symptom was noticed. It is thus manifest that in Plasmochin we have a drug with great potentialities. The cases quoted are no doubt too few for generalization, but they indicate at any rate the lines on which further investigations may usefully be made.

It may be remarked that red cell counts were also taken in the above cases but no untoward effect was noticed. One case of subtertian malaria (temperature chart No. 1) even showed an increase in them, as may be seen from the following table:—

Corps, 41.H.C. No...426.

Name... N.O. Kidar Singh. Age... 34. Service... 14
Disease... Malaria B.T. relapse. Date of Adm... 17.10.27.

No. 7432 Sepoy Luxman 2/4th Bombay Grenadiers (K. E. O.).

Day of treatment.	Treatment received.	Total R. B. C. count.	Parasites.
Nil ..	Nil ..	4,675,000	<i>P. falciparum</i> present.
1st ..	3 tablets Plasmochin Co. ..	4,533,333	Do.
2nd ..	6 tablets Plasmochin Co. ..	4,800,000	Do.
3rd ..	9 tablets Plasmochin Co. ..	5,000,000	Do.
4th ..	12 tablets Plasmochin Co. ..	4,600,000	Do.
5th ..	15 tablets Plasmochin Co. ..	4,500,000	Do.
6th ..	18 tablets Plasmochin Co. ..	4,750,000	No parasites seen.
8th ..	24 tablets Plasmochin Co. ..	5,500,000	Do.

The stimulating effect of quinine on the gravid uterus is well known and one is faced with a difficulty when a patient, resisting even small doses of quinine, reports for treatment. I had two such cases. One of these had been treated with two intravenous injections of quinine in Quetta and although her fever was suspended, on that account, had left headache behind it. Seven days later she got fever again, and it was then that I saw her first. On examination mixed *P. vivax* and *P. falciparum* infection was found in her blood. She would not take quinine. I put her on Plasmochin 1 tablet t.i.d. for the first three days, followed by Plasmochin Co. 1 tablet t.i.d.

injections were given, but malaria parasites were still found present. She was therefore put on stovarsol 2 tablets (gr. 4 each) t.i.d. and took in all 72 tablets at intervals. The fever subsided, but relapses occurred. She was then put on Esanophene, but since the small quantity of quinine in one pill of this compound brought back the above symptoms, this was also stopped. She was next put on a course of methylene blue. Seven grains of this were given in 1 grain doses. With this the fever subsided, but parasites were still found present. She was then given Plasmochin, which showed no untoward effect. She has now no parasites in her blood.

I may also quote the following three interesting cases in one of which (temperature chart No. II) Plasmochin proved a life saviour.

Corps...2/4th B.Grenadiers. No...7432 Name...Sep. Luxman. Age...18. Service...3/4
Disease...Malaria M.T. relapse. Date of Admission...12.12.27. Date of Discharge...5.1.28.

for seven days, after which her blood was found to have been sterilized of malarial infection. The treatment produced no untoward result. Seven days later she was safely delivered of a baby.

Other cases which give the doctor a most anxious time are those which have an idiosyncrasy for quinine and cannot stand even fractional doses of any quinine salt. I had two such cases last year but the one I mention below is the most susceptible patient I have ever come across:

Mrs. P. started malaria for the first time in this station last year. She could not stand even 1/10th gr. of quinine. The symptoms which were noticed after the administration of over 1 grain doses of quinine were (1) intense itching over the whole body, (2) urticaria, (3) redness of the whole skin and buccal mucous membrane, (4) abdominal pain, (5) diarrhoea, (6) hoarse voice and choking sensation in her throat, and (7) menorrhagia. Her blood on examination was found positive although she had taken 510 grains (34 gms.) of quinine sulphate orally. Whenever she had a severe attack of fever with vomiting, she was given sulpharsenol 0.48 gm. by injection, on which the intensity of the attack usually subsided. Four such

No. 426 N. Orderly Kidar Singh who had a previous history of severe malaria on 7th September, 1927, for which he had been put on post-hospital course of quinine, suffered on 17th October, 1927, from an attack of fever with rigor and vomiting. His blood showed *P. vivax* infection. He was taken into hospital the same day, treated with quinine hydrobromide gr. v injected intravenously at once, and thirty grains of quinine sulphate were prescribed orally per diem. The next day the injection was repeated. The temperature dropped to normal in the morning, but shot up to 103.4°F. in the evening. The 3rd injection was given on 20th October, 1927, but there was no relief and the temperature went up to 104°F. Quinine was continued orally but it failed hopelessly, the number of parasites being more numerous than before and the patient's condition became serious. On 21st October, 1927, he was put on Plasmochin 1 tablet t.i.d. After this treatment was continued for 3 days, the effect was striking, as the temperature chart shows. No more Plasmochin was given as it had run short in this hospital.

The two other cases were of more or less chronic variety. One was a European patient who was treated in Lahore with intravenous quinine, but was only temporarily relieved. When she came to Pishin *P. vivax* was found in her blood and she was getting fever

irregularly, in spite of Esanophele. She could not take quinine for long, therefore Plasmochin was started on 23rd October, 1927, she has had no fever so far since. The other case, Syaid Hussain, was a similar one. He had been treated with intramuscular injections of quinine on 16th October, 1927, and quinine orally, but without permanent relief. When he came to Pichin on 22nd October, 1927, he developed fever and *P. vivax* was found in his blood. He was put on Plasmochin on 21st October, 1927, as quinine had failed. He has since had no fever.

In addition to the above 11 cases, 13 more of different ages were successfully treated, varying from a baby of 16 days to a person aged 60 years. No untoward effect whatsoever was noticed in any one of them.

The dose of Plasmochin for an adult was in no case more than 0.06 gramme per diem and proportionately smaller doses according to age were prescribed for the younger.

I wish before I close to express my sense of indebtedness to Colonel A. H. Safford, A.D.M.S., Baluchistan District for every help, and to my assistant, Mr. Prem Singh, I.M.D., for his willing co-operation.

UREA-STIBOL IN THE TREATMENT OF KALA-AZAR.

By R. N. CHOPRA, M.A., M.D. (Cantab.),

LIEUT.-COL., I.M.S.,

J. C. GUPTA, M.B. (Cal.),

M. N. MULLICK, M.B. (Cal.),

and

A. K. DUTT GUPTA, M.B. (Cal.),

Carmichael Hospital for Tropical Diseases.

SINCE the introduction of von Heyden's compound, sodium acetyl-p-amino-phenyl-stibinate or "stibacetin," which was the first aromatic compound of antimony to be used in the treatment of leishmaniasis, many aromatic compounds of antimony have been introduced. Von Heyden also introduced sodium meta-chloro-para-acetyl-amino stibinate, known as No. 471 or "stibosan," and an amine salt of p-amino-phenyl-stibinic acid known as No. 693 both of which proved to be very effective in the treatment of kala-azar. In this country Brahmachari prepared a carbamide derivative of p-amino-phenyl-stibinic acid and called it "urea-stibamine" and the Union Drug Co., of Calcutta prepared the same compound and put it on the market under the name of "stiburea." Both these preparations have been extensively used in India in the treatment of kala-azar with excellent results. Urea-stibamine has been claimed by Brahmachari to be an ammonium salt of p-carbamino-phenyl stibinic acid, though Henry has criticised and doubted the constitutional formula given to it by the discoverer. Lately J. C. Das and S. C. Bhawal have introduced an allied compound which they sent to the senior author for pharmacological tests and therapeutic trials. The substance is called "urea-stibol" and it is claimed by its authors that it is a salt of urea and p-amino-phenyl-stibinic acid and is not

p-carbamino-phenyl-stibinate of ammonia which is the chemical name for "urea-stibamine."

Mr. Nihar Ranjan Chatterjee of the Department of Chemistry, Calcutta School of Tropical Medicine and Hygiene, has already shown (unpublished) that since urea can be completely removed from urea-stibamine by prolonged washing with absolute alcohol, this substance cannot be regarded as a definite chemical compound but is probably a complex salt of urea with p-amino-phenyl-stibinic acid.

We tested the pharmacological action and toxicity of "urea-stibol" and tried it in a series of cases of kala-azar. The results of the treatment were so striking that we thought it would be worth while bringing it to the notice of the medical profession on this side of India.

Pharmacological Action and Toxicity of Urea-stibol.—"Urea-stibol" is a white hygroscopic powder, easily soluble in water forming a clear deep brown solution. With dilute hydrochloric acid this solution forms a precipitate mostly soluble in excess of the acid.

Intravenous injections of "urea-stibol" in animals give very similar reactions to those given by urea-stibamine and the other pentavalent aromatic compounds of antimony. There is a fall of systemic blood pressure and a rise of the pulmonary pressure. The blood vessels of the liver and spleen dilate, the volume of these organs shows a remarkable increase, and their rhythmic movements are greatly augmented. The respiration is only slightly stimulated.

The toxicity of several batches of "urea-stibol" was tested by us. Its lethal dose in white mice varied between 220 to 230 mgm. per kilogram body weight when administered by intravenous injection.

Clinical Trials.—We tried "urea-stibol" in fifteen cases, details of which are given in the Table.

It will be seen that in nine cases the diagnosis was made by finding leishmania in the body, and in the other five by clinical and microscopical findings. The criterion of cure in most of the cases was by the general clinical manifestations such as disappearance of fever, increase in weight, decrease in size of the spleen and improvement in the leucocyte count. In very few of these cases was spleen puncture examination done to see if there were leishmania still present. The results, so far as they go in this small series of cases, show that "urea-stibol" is an efficacious remedy in the treatment of kala-azar. In two of these cases, Nos. 1 and 2, stiburea injections had been previously given with little benefit and a course of "urea-stibol" undoubtedly produced a clinical cure. A perusal of the remark column will show that the drug given in patients with bronchitis, diarrhoea and cancrum oris with benefit; no untoward effects whatever being noticed in these cases after injections. Some of these cases have now been under observation for three or four months and have shown no signs of relapse.

Case No. 15 is interesting. He came into the hospital suffering from continuous fever lasting 23 days. He gave a strongly positive antimony test and a doubtful aldehyde reaction, but unfortunately no examination for leishmania could be made to confirm the diagnosis of kala-azar. He gave a strongly positive Wassermann reaction. The patient was put on "urea-stibol" and after three injections the temperature came down to normal; the patient went out of hospital perfectly well after a course of ten injections.

It may be stated here that intravenous injections of this compound were very well borne. In none of these series of patients were any untoward symptoms produced by the injections. The dosage is the same as that with urea-stibamine.

SUMMARY AND CONCLUSION.

(1) Intravenous injections of "urea-stibol" in animals produce the same effects as with the other pentavalent aromatic compounds of antimony.

(2) The lethal dose of "urea-stibol" in white mice is 220 to 230 mg. per kilogram when given intravenously.

(3) Fourteen cases of kala-azar were treated with intravenous injections of "urea-stibol." The drug was well borne, gave rise to no untoward effects, and the results of treatment in this small series, were in no way inferior to those with "urea-stibamine" or "stiburea."

PATHOLOGICAL EVIDENCE BEARING ON THE INCIDENCE OF DISEASES IN BOMBAY.

By P. V. GHARPURE, M.D.,

Department of Pathology, Grant Medical College, Bombay.

(Being an abstract of the Lord Reay lectures, 1927, delivered at the Grant Medical College, on the 24th and 25th November, 1927.)

A STUDY of incidence of disease from a statistical point of view is obviously a complex one. One of the ways to attain this end with some success is to collect together reports from all important hospitals, medical schools, and all available data bearing on this question therefrom, together with collections from the practising profession and to put it together or compare it with the statistics published periodically by public health authorities. The averages obtained by such a combination will have some obvious defects, as the hospital data will be based on accurate laboratory findings, as compared with the public health statistics which are based on less accurate material. It is a well-known fact that in a vast country like India a few diseases are sharply localised to certain provinces only. On

the other hand other infectious diseases visit all parts of the country in an epidemic form in an almost cyclic order. For these and similar reasons an individual attempt to study the disease incidence in the whole of the country is bound to fail. It appears only possible to make individual attempts and to limit oneself to definite laboratory findings, and to study disease incidence so far as it concerns one place.

It may be interesting to note that the only available study of this kind has been carried out by Sir Leonard Rogers with regard to Calcutta, and published in the *Glasgow Medical Journal* in January 1925. I may add that I thoroughly appreciate the remark of the Editor of the *Indian Medical Gazette*, who has published extracts from the article above referred to,—“for accurate information regarding disease incidence in India we must turn to the post-mortem records of the medical colleges.”

In order therefore that uniformity in the observations may be maintained, I have precisely followed the lines adopted by Sir Leonard Rogers in his work. A copy of the tables prepared by Sir Leonard Rogers was forwarded to me by the Principal, King George's Medical College, Lucknow, in October 1925, “in order to extend the figures collected by Sir Leonard Rogers for post-mortems in Calcutta.”

The material available for this study here dates from the year 1877 and comprises records of properly recorded post-mortem examinations, numbering over six thousand.

The analysis of such a large number of post-mortems performed during a period of the last fifty years will yield, one may expect, fairly accurate results, though to the more critical some defects could be pointed out in such an analysis. In some respects the disease classification as inferred from post-mortem records may turn out to be misleading, as the hospital affiliated to this college cannot always have all cases dying in the hospital put at the disposal of the pathologist for a post-mortem examination, owing to religious and social conditions; secondly, Bombay has a separate hospital for infectious diseases belonging to the City Municipality, and hence a very small number of post-mortems are recorded here of cases of such diseases as small-pox, cholera, plague, relapsing fever, cerebro-spinal meningitis, etc., in spite of the fact that the city has had many epidemics during the years under consideration.

In the age statistics the very small number below ten years in spite of the highest mortality existing below ten years is easily explained by the fact that quite a negligible number of dead bodies of infants are available for post-mortem examination, again through religious and social obstacles.

Thus it will be clear that the records obtained in this way may not serve the purpose of giving an absolute indication of incidence of disease as responsible for death rates in a particular area,

town, or presidency, and much less for the whole country. If hospital registers recording deaths were also utilised at the same time probably the figures would be different.

At the same time the figures may be comparable with those obtained by Sir Leonard Rogers in Calcutta, working under practically similar social and religious conditions; suffice it here to set out on exactly similar lines the analysis of records collected here.

This is my reason for publishing this article.

The percentages of post-mortems in the systemic classification are liable to certain variation. The following table shows the percentages of systemic diseases of every fifth year.

Dysenteries form the largest group, nearly making up half the total. Malarial fevers form nearly a third of the total. Kala-azar is only occasionally seen in Bombay, and only amongst immigrants. The Bombay figures, it will be seen, vary widely from those for Calcutta, probably because of the exclusion of cholera and plague as infectious diseases treated elsewhere. The same reason might explain the relatively small total figure for deaths from tropical diseases in Bombay. Deficiency diseases are practically absent in these series owing to the fact that the majority of the patients admitted into the hospital are from the districts where in the ordinary course of their dietary they use fresh

		1885	1890	1895	1900	1905	1910	1915	1920	1925
Tropical diseases	16·8	13	14	18	13	16·5	8	7	16·8
General diseases	23·2	13	5	12	10	6·5	8	8	12
Tuberculosis	24	9	22	22·5	27·5	28·5	20	25	16·8
Circulatory	2·4	6	4	4·5	7	15·5	9	3	8
Respiratory	13·6	22	7	12	27	20	26	23	28
Digestive	14·4	16	9	3	2	8	6	7	3·2
Urinary	1·6	4	13	4·5	4·5	3·5	1	2	4
Nervous	6·4	8	3	7·5	4·5	4·5	9	6	6·4
Malignant	2·4	2	5	0	2	1·5	2	0	1·6
Remainder	9·6	20	21	7·5	5	10	5	5	2·4

Under some headings a great variation is seen in different years. At the same time one must note that practically in every year under consideration at least a few post-mortems on every systemic disease have been called for. Hence combining the records of a large number of years is only going to leave a negligible error, if any.

TABLE I.

Percentage of Total Mortality due to Tropical Diseases.

Disease.	6,336 Bombay Post-mortems.	1,600 Calcutta. Post-mortems
Malaria ..	3·12	1·56
Kala-azar ..	0·08	8·06
Plague ..	0·87	0·37
Cholera ..	0·32	9·69
Amœbic dysentery ..	4·50	5·69
Bacillary dysentery ..	1·31	4·12
Amœbic liver abscess ..	2·70	2·69
Ankylostomiasis ..	0·186	0·130
Beri-beri ..	0·13	0·37
Leprosy ..	0·20	..
Relapsing fever ..	0·26	..
TOTAL ..	13·80	33·43

vegetables, unboiled milk and unpolished rice. The very small number recorded have nearly always been from amongst the Japanese.

Differentiating between amœbic and bacillary dysentery from post-mortem notes has been difficult. Whenever the large bowel has been described as the seat of discrete ulcers with healthy mucous membrane between I have recorded the condition under amœbic dysentery; on the other hand a diffuse gangrenous colitis I have always counted under bacillary dysentery.

Ankylostomiasis is probably commoner than shown in the above table. The above figures refer only to such of the ankylostomiasis cases as have died of this infection.

The Bombay series also show considerable excess in general and especially tubercular disease and diseases of the respiratory system. All the other groups show a smaller percentage than in the Calcutta figures.

Anæmia shows nearly the same frequency as in the London series. Leukæmia and diabetes are very rare; tetanus and typhoid have given much higher figures than in the other two series. It is interesting to note that out of the 28 cases recorded as tetanus 24 cases were recorded between 1877

TABLE II.

Age Incidence per cent of Total Medical Post-mortems.

Percentage.	BOMBAY.		CALCUTTA		ST. MARY'S HOSPITAL, LONDON.	
	All ages.	Over ten.	All ages.	Over ten.	All ages.	Over ten.
Up to 10	0.78	2.5	16.9
11 to 20	10.7	10.77	13.4	13.8	10.2	12.2
21 to 30	34.2	35.1	35.3	36.3	12.1	14.6
31 to 40	28.6	29.0	27.4	28.1	12.3	14.8
41 to 50	15.8	15.9	13.3	13.7	16.5	19.9
51 to 60	7.92	8.02	5.8	6.0	20.0	24.1
Over 60	3.16	3.19	1.9	2.0	12.0	14.4
Over 50	11.0	11.22	7.7	8.0	32.0	38.5
Over 40	26.9	27.1	21.0	21.7	48.5	58.4

TABLE III.

Percentage of Deaths in the Main Groups of Diseases.

Diseases.	Bombay.	Calcutta.	London.
General	5.37	9.23	6.10
Tuberculosis ..	25.36	21.93	13.40
Circulatory ..	6.05	10.50	20.30

Digestive	8.79	12.0	7.50
Urinary	4.185	6.35	8.60
Nervous	5.502	7.41	11.9
Malignant diseases ..	1.49	4.59	13.8
Remainder	4.95	0.84	1.60

TABLE IV AND V.

Percentage of General Diseases including Tuberculosis.

Diseases.	Bombay.	Calcutta.	London.
Anæmia	1.44	2.34	1.50
Leukæmia	0.126	0.27	1.70
Diabetes	0.14	0.18	0.70
Diphtheria	0.18	0.50
Septicæmia	1.39	3.00	0.50
Tetanus	0.44	2.05	0.10
Typhoid	0.71	1.21	0.3
Syphilis	1.17
<i>Tuberculosis.</i>			
General	2.56	3.09	3.50
Meningitis	0.20	1.04	2.40
Pulmonary	19.30	16.10	5.40
Primary intestinal. ..	1.44	1.04	0.0
Peritonitis	0.47	0.05	0.80
Other focus ...	1.59	0.09	1.0

and 1905, only 3 between 1905 and 1924, and only 1 in 1924-26. This shows how remarkable is the effect of the antitoxin as a prophylactic measure, and how it has reduced the incidence and deaths due to tetanus in recent years. In typhoid fever we find the cases have been evenly distributed throughout the fifty years. In a good number of cases the cause of death has been put down as syphilis and the notes give ample evidence in favour of such a diagnosis, e.g., multiple gummata in the internal organs including the central nervous system; hence I have thought it desirable to put syphilis as a separate heading.

Diabetes is rarely recorded, mainly owing to the fact that the hospital admissions are mainly from the poorer classes. About a dozen cases, mostly of old standing diabetes come to the hospital in a year but leave the hospital before the fatal termination.

As regards tuberculosis one finds the same ratio as described by Sir Leonard Rogers. Pulmonary tuberculosis being the most common, forms four-fifths of the total number of deaths due to tuberculosis. On carefully going over the notes and minutely examining tissues at over 200 autopsies during the past few years I am led to think that every tuberculosis case is a chronic one with very little or no fibrosis, ending either by complications like pneumonia or by an acute dissemination of the chronic focus all over the body. The commonest mode of dissemination seems to be by the bronchial tree in either lung from a pre-existing pulmonary focus; next common most seems to be lymphatic dissemination; whilst dissemination by the vascular stream is the least common. It is further interesting to know that in spite of minute tubercles being formed all over the body the meninges especially escape. One or both tonsils have always shown a tuberculous

focus of a comparatively recent formation in every case of tuberculosis. The distal one inch of the appendix has never been seen to be the seat of tuberculous infection; the commonest place where the appendix is affected is its cæcal end. In a larger proportion of tuberculosis cases wherein intestinal lesions are seen the colon and the rectum have shown ulceration. Genito-urinary tuberculosis is comparatively rarely met with here, the museum in this college having only a dozen specimens illustrating tuberculosis of the kidney.

Other findings relating to the heading tuberculosis as recorded in Calcutta are to a great extent applicable to Bombay also.

During such periods of the year when acute pulmonary diseases like pneumonia are responsible for a large number of deaths, tuberculosis is comparatively less common as a cause of death as noticed in the post-mortem room.

TABLE VI.

Percentages of Respiratory Diseases.

	Bombay.	Calcutta.	London.
<i>Respiratory:—</i>			
Lobar pneumonia	12.91	16.03	4.2
Broncho-pneumonia.	4.74	5.80	6.1
Bronchitis ..	3.75	3.00	4.7
Pleurisy and empyema.	1.14	1.30	1.2
Others ..	1.2	1.0	0.6

Respiratory diseases appear to be responsible for one-fourth of the total number under consideration (23.75 per cent.),—a much higher figure than the percentage in the London series, being nearly one and a half times the latter. Lobar pneumonia is the commonest, whilst basal pneumonia has nearly the same incidence in all the three series.

TABLE VII.

Percentages of Circulatory Diseases.

	Bombay.	Calcutta.	London.
<i>Circulatory:—</i>			
Ulcerative endocarditis.	0.205	1.05	2.6
Rheumatic endocarditis.	0.56	0.00	3.7
Aortic valve disease.	0.93	2.73	2.6
Mitral valve disease.	1.04	0.93	4.3
Pericarditis ..	0.28	0.75	0.4
Atheroma ..	1.02	1.41	2.4
Aneurysm ..	0.79	0.59	1.1
Others ..	1.20	1.59	1.1

There are thirty-six cases recorded of rheumatic endocarditis. In the absence of a bacterio-

logical finding I would not go further in drawing conclusions. As regards valvular diseases, the affections of the mitral valve are at least equal to if not commoner than the affections of the aortic valve. Aneurysm and atheroma as a cause of death are less common in my series as compared with the Calcutta figures. Very few cases are recorded as occurring above the age of 40; the most common age incidence recorded varies between 28 and 35 years. There are extremely few instances of congenital abnormality. Syphilitic changes in the wall of a thickened or irregular aorta or in the wall of an aneurysm are very common, as seen by me in recent years. Special mention may be made of a very rare case of an aneurysm recorded in 1925. It was discovered in a male aged 28, who had been admitted into the hospital quite unconscious and who died within 36 hours of admission. It was a dissecting aneurysm commencing from the aortic orifice, extending to the bifurcation of the aorta. The orifice through which the blood had traversed had completely closed, so that the aorta was divided into a very small channel for the blood and the large aneurysmal sac, completely closed at either end.

One may not be wrong in stating that, in general terms, atheroma is met with at all ages ranging from 20 years onwards. The age incidence of valvular diseases as found in the Bombay series is chiefly between 28 and 35.

TABLE VIII.

Percentages of Digestive Diseases.

	Bombay.	Calcutta.	London.
<i>Digestive:—</i>			
Gastric and duodenal ulcers.	0.22	0.92	2.1
Enteritis ..	3.36	1.42	2.0
Cirrhosis of the Liver.	2.01	5.91	1.3
Others ..	3.19	3.75	2.1

Owing to the fact that the details about digestive disorders are less minutely recorded in the post-mortem records here, a comparative study of the different diseases must be postponed. From the total one may say that digestive diseases are equally responsible for deaths as in the London series, and less common as compared with the Calcutta series.

Post-mortems done on subjects below 10 years are so few that I am unable to say anything about gastro-intestinal disturbances in children.

The commonest type of cirrhosis of the liver seen here is the multi-lobular (alcoholic?) variety. Chronic malarial infection is observed to produce a unilobular type of cirrhosis. Syphilitic scarring of the liver is very common. Biliary cirrhosis is less common than the alcoholic. In both the

biliary and alcoholic varieties in a large proportion of the cases the death has been due directly to the cirrhotic process. Chronic or acute ulceration of the large bowel has not been observed coincident with cirrhosis of the liver. Thus from the records available here much light cannot be thrown on any newer conception of cirrhosis of the liver.

TABLE IX.

Percentages of Urinary Diseases.

	Bombay.	Calcutta.	London.
<i>Urinary:—</i>			
Parenchymatous			
nephritis ..	1'865	1'96	2'3
Granular kidney	1'185	3'46	5'4
Others ..	1'14	0'93	0'9

Kidney disease by itself as a cause of death is very rare. It is a common experience of anybody who has worked sufficiently long in the post-mortem room that the kidneys show at all autopsies parenchymatous or interstitial changes to a greater or less degree. As will be seen from the above table all forms seem to be equally responsible for death. A typically chronic parenchymatous nephritis, apart from its being a cause of death, has been only noticed by me twice in the last 600 post-mortems; and was coincident with chronic tuberculosis of the lungs; atheromatous changes in the arteries however extensive are never accompanied by interstitial changes in the kidney. Kidney disease shows the same or a slightly lower percentage as compared with the Calcutta series.

TABLE X.

Percentages of Nervous System Diseases.

	Bombay.	Calcutta.	London.
<i>Nervous:—</i>			
Meningitis ..	1'568	3'29	2'40
Apoplexy ..	2'196	1'96	6'2
Others ..	1'725	2'16	3'3

The frequency of nervous diseases is in close parallel with the Calcutta series. Pneumococcal meningitis is often seen. Streptococci have not been discovered to be the cause of meningitis even once. Meningococcal meningitis is not at all uncommon. To give a single illustration, between June 1921 and July 1922, I came across in a single ward 35 cases of meningococcal meningitis as diagnosed by examination of the cerebrospinal fluid. Certainly, out of the two, pneumococcal and meningococcal meningitis, the former is the more fatal.

TABLE XI.

Malignant Growths (Percentage) in Bombay and Calcutta Post-mortems.

	Bombay Cases 6,336	Calcutta Cases 1,600
<i>Sarcoma:—</i>		
Lympho-Sarcoma ..	5	12
Others ..	12	10
<i>Carcinoma:—</i>		
Stomach ..	13	3
Gall-bladder ..	2	10
Primary of the Liver ..	2	6
Pancreas ..	7	4
Oesophagus ..	5	0
Large bowel ..	5	2
Female genitalia ..	5	2
Breast ..	1	0
Lungs ..	39	0
Others ..	1	0
TOTAL ..	97	49

As far as one can see from the above figures, post-mortem examinations on malignant disease cases are very rare, the total percentage in the Bombay series being 1.49 as against 4.59 in the Calcutta series, and 13.8 in the London series think however, that generalisations about the frequency of the different malignant diseases may be misleading.

TABLE XII.

Incidence of Malignant and Innocent Tumours in Bombay, Calcutta and London.

In the following table are analysed a thousand tumours sectioned at the Grant Medical College, Bombay.

Innocent Tumours.	1,000 Bombay cases.	1,190 Calcutta cases.	1,000 London cases.
1. Connective Tissue—			
Fibroma ..	114	63 0	29
Fibro-myxoma ..	15	52'9	10

Total malignant, epithelial ..	430	394.8	474
Total innocent tumours all forms ..	385	421.0	435
Total innocent, epithelial ..	128	84.0	158

From the figures given in the tables above it will be seen that many facts referred to by Sir Leonard Rogers are borne out. The supposed immunity of the uncivilised races can well be disproved by the fact that in my series 1.49 per cent. is recorded for malignant disease in the post-mortems, as compared with 4.59 per cent. in Calcutta and 13.8 per cent. in London. My figures, however, are greatly modified by the circumstance that most of the malignant disease cases that undergo operation leave the hospital and cannot be subsequently traced, and as a rule do not return for operation for recurrence. One will not be far from right in saying that many cases must be recurring and dying outside the hospital, thus explaining the very small number of post-mortems. On the other hand the analysis of the sections examined at this college shows a close parallelism with the Calcutta figures. On an average about 100 tumours are sectioned per year up to now. This number is gradually increasing. However, these cannot be the absolute figures, as sometimes well defined benign or malignant tumours, clinically decisive, do not come to the pathologist for section. Taking into consideration this error or omission the figures given above will certainly give a fairly accurate idea of the frequency of tumours. My figures are in every respect higher than those of the Calcutta series, except for innocent tumours; relatively the total malignant tumours exceed the total innocent tumours. Squamous epithelioma and carcinoma are nearly equally common. Epithelial tumours in general exceed the connective tissue tumours by a large percentage. From the point of view of age incidence and its bearing on the occurrence of tumours in general my findings coincide with those of Sir Leonard Rogers. Tumours are seen at a comparatively early age here. The average may be put as occurring between 28 and 35 years. Cases above 50 very rarely occur. The number of tumours examined by me during the last few years is comparatively small, viz., one-third of the total number of cases examined. I have not so far gone into further details about their relations to organs, age, nationality, multiplicity and histological nature. I have already published a small paper embodying my conclusions about the incidence of primary carcinoma as it affects the liver, gall-bladder, pancreas and the stomach, in the *Indian Medical Gazette* for June 1927. I am carrying on further observations in this connection. To conclude about malignant disease affecting individual organs it will require probably many years to collect enough facts for analysis.

This paper may be taken as only a preliminary contribution to this subject, which is very vast and not likely to be completed satisfactorily in a short time, especially when the sources of the material are so complex.

Before concluding I desire to express my gratitude to the Professor of Pathology, Grant Medical College, for allowing me to carry on this

work and helping me at every stage, and to the other staff of the department for the whole-hearted assistance given to me by them.

THE TREATMENT OF CHOLERA BY ACID AND CRESOL.

By F. J. PALMER, F.R.C.S.I., Lt.-Col., R.A.M.C. (retd.).

IN the *Indian Medical Gazette* for August 1924, the writer published a paper on the treatment of cholera by cresol, and on the general principles which, in his opinion, should guide one in the treatment of any case of cholera.

In the same journal for April 1925, a further paper was published on the treatment of cholera by cresol and acid. The latter treatment was then only in the tentative stage, and only a small number of cases had been treated by the method. The writer had, however, been much impressed by the results in the earlier cases treated, and has continued the same treatment, with gradual improvement of the method during the cholera seasons of 1925, 1926 and 1927.

The treatment and principles of application are exactly the same as in the paper of April 1925, but the dose of acid has been gradually and cautiously increased as experience showed that no ill effects had been produced by it in the smaller doses.

The following instructions were issued to all medical subordinates on 25th January, 1927:—

Treatment of Cholera, 1927. Standard cresol mixture m 1 in ounce of water (Sanitol brand if possible), to which acid is subsequently added. the sooner before use the better.

1 to 3 years	1 minim cresol	3 m	acid sulph.	aromat 1 oz. water.
3 to 6 "	2 "	4 m	" "	" 2 " "
6 to 9 "	2 "	6 m	" "	" 3 " "
9 to 12 "	3 "	8 m	" "	" 3 " "
12 to adult	4 to 5 "	10 to 15 m	" "	" 4 " "

according to age and weight.

Increased dosage according to age and size is secured by increasing the amount taken in proportion to the bowel area, and not by increasing the strength of the cresol in the mixture.

A dose every $\frac{1}{4}$ hour for 8 doses, that is 2 hours; and afterwards every $\frac{1}{2}$ hour for 4 doses, another 2 hours; making 12 doses in all spread over 4 hours.

When this period is over the acid is stopped, and the cresol alone given hourly, unless there is a further tendency of the pulse to fail, or failure for a second time of a returning one, when it may be given again for a few doses. It may also be resumed for a few doses if further diarrhoea occurs, and the motions are found to be alkaline to litmus paper.

Second day, or after 24 hours, cresol 2 hourly.

Third day, or after 48 hours, cresol 3 hourly.

Any tendency to relapse on the second or third day, which is rare, to be met by addition of acid for a few doses.

If vomiting or retching constant, give for adults Tinct. Opii m 20 or 25, or Tinct. Chloroformi et Morphine Co. m 15 to enable mixture of acid and cresol to be retained.

Opium is sometimes useful in the restlessness of late cases, to induce sleep, lessen vomiting and retching, etc., but should not be given, if possible, until there is evidence that the bowel has been completely emptied, and, even then, only in very special cases.

Plenty of tepid water to be given early between the doses of acid and cresol mixture. At this stage there is a good deal of thirst, and it is easy to induce patients to swallow fluid; later it is often very difficult. The head should always be slightly lifted by the left palm when administering fluid or medicine, and a feeding cup used. Neglect of this precaution may lead to a fatal issue at times, from fluid entering the lung.

In my experience in dealing with Indians this small point requires constant stressing and repetition, and I have often had to check attendants from pouring medicine or fluid into the open mouth of a recumbent, collapsed, and sometimes almost senseless, patient.

In dry cholera cases with one or two attacks of vomiting, early purging, and rapid collapse, an injection of pituitrin may be given and if this does not quickly produce evacuations, Tabloid elaterin (four tabloids, gr. 1/40, B. W. & Co. for an adult), or 5 grains of calomel may be given. The writer has not so far had any opportunity of testing this plan.

Stimulation by adrenalin and camphor in severe cases, as already laid down, and general principles to be followed.

For the benefit of those who have not seen my paper of August 1924, I quote the following paragraph from it.

"During the stage of collapse, three to eight minims of solution of adrenalin chloride, 1 in 1,000, may be given hypodermically or intramuscularly every two hours, or slightly more often. In marked cases of collapse camphor, one-quarter to one grain, according to age, may be given in a similar manner. In most cases in an adult, however, I prefer to give half a grain of camphor and repeat in half an hour if necessary, no further dose to be given under two hours."

I am rather loath to introduce large doses of any stimulant, no matter how desirable otherwise, in a patient whose kidney function is in abeyance, and rarely give more than three doses

of either stimulant. Experience has seemed to show that cases receiving repeated doses of adrenalin have not done as well as those receiving only a few. This may of course be due to the fact that only the most severe cases were so treated, but it may be due to the fact that relaxed vessels offer less resistance to blood passage and so conserve heart energy.

The quality of the cresol used is of importance. I quote from my first paper on this subject. "Some of these preparations I have seen are highly unsuited for internal use, and seem to me to consist chiefly of crude carbolic acid. It is stated that para-cresol is a powerful poison. A good variety of cresol for internal use should be thoroughly miscible with cold water, producing an emulsion resembling much watered milk. No globules, however minute, of tarry fluid should remain in suspension, this being generally a characteristic of the inferior brands. The preparation, in other words, should make a perfect emulsion. It should have a slight, not unduly pungent, tarry taste, but should not taste at all of carbolic acid."

"Preparations forming a thin watery, very slightly milky fluid, should not be used internally. These are generally of the crude carbolic type."

The acid should be added to the cresol solution immediately, or as shortly before use as possible, to prevent separation out of the cresol. I have tested many brands of cresol in this manner by adding acid, and the one which results in least separation of tarry particles, even after some interval has elapsed, is "Sanitol" a preparation sold by Frank Ross and Co., Calcutta. (Usual disclaimer.) This I have found preferable to any brand yet tried. I should hazard the guess that the resistance of this emulsion to acid is possibly due to the fact that it has been emulsified with some resin. Particles emulsified by soap or alkali would more quickly run together on addition of acid.

So far 167 cases have been treated by this method during the past three years, with 134 recoveries and 33 deaths, a mortality of 19.7 per cent.

During the past year, with the acid dosage as now laid down, there were 27 cases with 5 deaths, a mortality of 18.5 per cent. Two of these cases had received two doses of vaccine a short time before, and one had been inoculated once. All three recovered, a fact of little significance in view of the Madras figures for 1926, and the writer's personal experience.

There were 9 completely pulseless cases when first seen, of which 4 died, a mortality of 44.4 per cent, and 12 semi-collapsed cases of which one died. It is doubtful if this one is rightly placed, for the writer has on several occasions seen one of his subordinates report a pulse in a case in which the most painstaking personal examination failed to detect one. In such cases the

pulse in the observer's finger tips, intensely anxious to detect the faintest impression, is mistaken for that of the patient.

One of the fatal cases had a hæmoglobin index of 30 per cent, and was being treated for anæmia when cholera supervened. Another had been ill for 24 hours, and was only seen an hour before death. In a third case pulse and urine had returned, but the child died next day with symptoms suggestive of perforation. Inquiry elicited the fact that it had suffered from a quinine-resistant fever for a week before the onset of cholera, probably enteric. I mention these to show that the results as regards cholera are even better than they seem, and to show that no "cooking" of results has taken place. On the garden on which the writer resides there have been in 1927 seven cases with one death, and that the anæmia case above referred to.

The writer has used the above treatment, slightly modified according to the severity of the case, for bacillary dysentery for the past three years, and considers it at least equal, if not superior, to any other at present in vogue.

In the case of a severe infection the doses should be given at least half hourly for six or eight doses, and thereafter hourly for the first 24 hours, being continued two hourly and three hourly for the second and third days respectively. Administration should then be stopped. The guiding idea is that if the specific bacilli can be hindered in their rapid multiplication at an early stage, necrosis of the mucous membrane will not take place to any great extent, and time will be given for the production of natural protective substances.

Administration is stopped at the end of three days to counteract any tendency towards the evolution of a cresol and acid-"fast" organism in the progeny of those bacilli which may survive the early intensive treatment. Any tendency to relapse which may then occur can be dealt with by the original method of attack with more hope of success.

In initially milder cases it will not be necessary to give the doses as frequently as in the more severe types.

A similar mixture is the routine method of treating diarrhoea on all the gardens of which I have charge. It seems efficacious, possibly lessens the number of carriers, and many intestinal worms have been reported to me as expelled after its use.

Some sixteen years ago the writer first used cresol lavage in a case of sprue, steadily going to the bad, on which he had performed appendicostomy for the purpose. The result was complete cure. That was long before I had dreamed of oral administration. In the past few years I have treated two cases of typical sprue with acid and cresol with complete success. In a third case it failed, but certainly seems worth a trial.

Indian Medical Gazette.

MAY.

HOOKWORM INFECTION IN INDIA.

AN exceedingly important memoir on hookworm infection in India is that by Dr. Asa C. Chandler in the January 1928 number of the *Indian Journal of Medical Research* (Vol. XV, No. 3, p. 695). As only a few of our readers see that journal, perhaps we may be excused for reviewing this contribution to an important subject at length. Dr. Chandler has been working for the last three years at the Calcutta School of Tropical Medicine under the grant from the Indian Jute Mills Association, his research work also being partly financed by the Indian Research Fund Association, and his recent appointment to the Rice Institute in Texas robs India of one of her keenest and most enthusiastic research workers.

Method of Investigation.—The campaign was planned to cover the whole of India and Burma with a view to determining the extent and severity of hookworm infestation in this country, and its importance in medical practice in India. The procedure adopted for each province was as follows. The *Gazetteer* was first carefully studied with regard to the climatic and physical features, etc., of the province, and certain rural districts and towns were picked out as being most typical of the province. The local authorities were then communicated with, and in most instances gave very valuable and enthusiastic help to the enquiry. An advance party then left Calcutta to visit in turn each selected centre or rural area. Field men were sent out and distributed slips of paper with the age, caste, and sex of the individuals concerned, persons of all ages and castes and of both sexes being taken. These individuals were instructed to place the slip of paper beside the stool when passed at the defæcation site the next morning, when sweepers, who had been especially trained for the work, collected each stool and paper in turn. In this way it was usually possible to get from 75 to 100 stools from known individuals in each village, whilst other stools from non-identified individuals were also collected from the defæcation sites.

The stools were railed to Calcutta, and on receipt were immediately placed in the refrigerator room. Each was examined by Lane's direct centrifugal flotation method, and if found to be positive egg counts were made by Stoll's dilution egg count method. Dr. Chandler is convinced that very few infections were overlooked; the ova were well preserved and very few showed signs of degeneration.

In the meantime the field party collected observations and made maps of the locality, showing relationship of defæcation areas to houses, tanks, wells, etc. Copious notes were taken in all instances of the defæcation and other habits of the

people; the water supply was carefully studied, notes taken of the types of houses and their construction. The question of soil infestation was studied on the spot and soil samples collected and railed to Calcutta. The field party visited each province in turn.

As soon as the preliminary knowledge had been gained, Dr. Chandler then made a personal visit to each area in turn to observe conditions at first hand. In this way it proved possible to make a complete survey of India and Burma within the short space of three years. Whilst he does not claim that this method is infallible, Dr. Chandler claims—with some degree of confidence—that the method does afford an index of the local infestation, by which one locality can be compared with another.

General.—India is a vast country, and every possible variety of climate is to be encountered within her borders, whilst rainfall conditions vary very widely. It was found that both the total annual amount of rain and its distribution throughout the year have an important bearing on the propagation of hookworm infections. When the total rainfall falls below 40 inches in the year, there may be a high incidence of light infections, but heavy or even moderate infections are absent or very rare, and consequently there is little or no hookworm disease. If the total rainfall is so distributed that not more than 5 or 6 inches fall in any one month, the incidence is small also, whereas in places where 9 or 10 inches fall within any one month, the incidence of infestation may reach 70 to 80 per cent. or more. The larger the number of months in the year during which the ground is kept practically continuously moist, the greater is the amount of hookworm infection which will occur. Hookworm infections are rapidly lost when re-infection is stopped; three months of dry weather appear to be sufficient to ensure a loss of about 50 per cent. of the worms harboured, 60 per cent. are lost in six months, and 65 per cent. in nine months. The consequence of this is that the time during which hookworm infection can be acquired is reduced in India from 12 months to a period varying from 2 to 8 months for different provinces. A dry season of from 6 to 8 months has practically the same effect as mass treatment would have on the population, and although throughout India hookworm infestation is excessively common, yet heavy infections are rare, and hookworm disease—as apart from infestation—is uncommon. We have been accustomed for many years to think of hookworm infection as being one of the chief scourges of India. Actually, it is apparently a relatively unimportant cause of disease in this country—except in certain specified areas.

Since it takes about six weeks after infection for the ova to begin to appear in the patient's faeces, the egg counts begin to show the effect of the new acquisitions about six weeks after the onset of the rainy season, and cease about six weeks after the dry weather has set in.

Other Epidemiological Factors.—Occupation does not play a very important part in hookworm infection in this country, since 90 per cent. of its inhabitants are rural labourers. Unlike China, where human faeces are extensively used for manure, in India human faeces are not so employed, and hence the Indian problem is a much less difficult one than the corresponding one in China. Soil pollution on the other hand is almost universal in India, since the villagers of India habitually defæcate on the surface of the ground somewhere near the villages. In the delta division of Burma, which is habitually flooded during the monsoon, latrines of a primitive type are in use by most of the inhabitants, and in some parts of Eastern Bengal primitive latrines are used by the women and children. In many parts of South India a piece of ground is set aside in the village, surrounded by low walls, for women, and is called a latrine; actually it is far more dangerous than defæcation in the open.

A curious point which comes out in the enquiry is that the normal type of stool in India is not the formed one, which is considered characteristic of European countries, but a pasty one, which is not formed. This is true of all parts of the country and of all its races. It is obvious that the more concentrated the defæcation area, the greater the danger of contact with infested ground when the area is visited. The vast majority of infections are acquired when standing or sitting on infected ground during the act of defæcation. Even the use of a raised root of a tree, or of a low horizontal branch, in so far as it is efficient in keeping the feet off polluted soil during the act of defæcation, is a powerful factor in controlling hookworm infection.

With regard to occupation, sweepers and sewage farm coolies, owing to the nature of their duties, are continuously exposed to infection, but the infections are usually mild. Tea garden coolies are especially prone to infection, owing to their habit of defæcating in the tea bush areas; whilst coal miners are also especially exposed to infection from soil pollution in the underground galleries. The wearing of footgear of any type protects very remarkably against infection; thus in the United Provinces, Central India, and the Shan States where footgear of a some type or other is almost universally worn, the incidence is extremely low. Domestic animals possibly help to spread hookworm infection by eating faeces, and passing the ova out in their stools; of such carriers pigs are especially important, and also dogs, though cattle and buffaloes also devour human stools and are under suspicion. In the coal mines the one factor which preserves the health of the miners is the presence of cockroaches; these devour the stools deposited in the underground workings and the ova are destroyed by the action of the grinding organs in the proventriculus; it is rather strange thus to encounter the cockroach in its rôle of 'the friend of man.' Dung-beetles on the contrary are a powerful factor in the development of hookworm larvæ,

for they mix the faeces more intimately with the soil and thus help to disseminate the infection.

The character of the soil concerned has important bearings. Clay and black soils are unfavourable towards dissemination of the disease, whilst sandy and porous soils are favourable. Black-cotton soil is especially unfavourable. Salt has a destructive action on hookworm larvæ, and in the Sunderbans stools deposited near the water are reached at high tide and rendered innocuous. The spread of artificial irrigation in India does not appear to be followed by more intensive hookworm infection, a most re-assuring finding, since more than one prophet has foretold that the extension of big irrigation schemes in India would be followed by the spread of hookworm disease. In most parts of India both sexes are about equally affected, but it not infrequently happens that special latrine sites are set aside for females, whereas the males use more open and unreserved ground, and in such places females may suffer more than males.

Age has an important bearing on the epidemiology of the disease. Children commence to become infected soon after they begin to run about, and with increasing age and increasing exposure to infection there is a corresponding increase in the degree of infection with age.

Species.—In Southern India *Necator americanus* is practically the only species present, less than 5 per cent. of the worms examined being *Ancylostoma duodenale*. In Bengal the prevalence of the latter species rises to 20 per cent. In Bihar, according to Korke, *Ancylostoma duodenale* is the more prevalent species. *Ancylostoma braziliense* has not yet been recorded from man in India, but occurs in Burma, Malaya, and the Islands in the Bay of Bengal.

Grades of Infection.—This subject is all-important, and Dr. Chandler divides the degree of infection present into seven grades, as follows:—

- Grade 1; entirely negative.
- Grade 2; less than 100 eggs per gramme.
- Grade 3; 100 to 500 eggs per gramme.
- Grade 4; 500 to 2,000 eggs per gramme.
- Grade 5; 2,000 to 5,000 eggs per gramme.
- Grade 6; 5,000 to 10,000 eggs per gramme.
- Grade 7; over 10,000 eggs per gramme.

Roughly speaking 100 eggs per gramme represent an infestation with about 8 worms, whilst there is some evidence that *Necator americanus* deposits fewer ova than does *Ancylostoma duodenale*. Of course, the vitality and degree of resistance of the patient are important factors in determining whether light infections may give rise to anaemia and other symptoms, and there has been much discussion as to the correlation, if any, between the degree of infection and that of the anaemia present. For all practical purposes, concludes Dr. Chandler, as far as India is concerned, grades 1, 2, and 3 are negligible, even in children. It is only when the egg count rises to a higher figure than 500 per gramme that the infestation causes obvious symptoms. On the other hand group 3, whilst negligible clinically, may be of

importance in spreading the infection. Group 4 individuals are but little indisposed—certainly much less so than the victims of tuberculosis or malarial cachexia; group 5 individuals show mild symptoms, especially loss of energy and vitality, whilst in groups 6 and 7 symptoms are marked or even severe. Dr. Chandler here introduces an 'index of infection' for a community, which is obtained by multiplying the average egg counts (i.e., 1/100th of the eggs per gramme) of the infected individuals by the square of the percentage and getting the square root in order to bring the figures within a reasonable range. This index he proceeds to apply to the different areas of India, and concludes that when it falls below a figure of 200 the infestations are so light as to be negligible. If the index is above 300, then hookworm infection becomes a public health problem of importance for the area concerned.

Provinces.—The outstanding result of investigations in Southern India, and of our own, in all parts of India' writes Dr. Chandler, 'is the indisputable demonstration of the fact that, in spite of a very high incidence of infections in some parts of the country, hookworm disease is practically non-existent in most places, and limited to a relatively small percentage of the population even in the most severely affected areas. Only in a very few localities in India (some places in Burma, and on some Darjeeling and Dooars tea estates) does the index of infection exceed 400.' These figures may be contrasted with those for the West Indies, where the index approaches 600, and Alabama where it exceeds 500.

In Burma, results are extremely diverse. In the delta region, which is flooded every year, the local inhabitants use primitive latrines, and the infection rate is low. The immigrant Indians however do not; and these infections were the heaviest encountered anywhere in India. The general index for the province is from 108 to 176, and therefore negligible. In the northern tracts and the dry zones there is practically no hookworm disease.

In Assam conditions are not good, and the infection is particularly high on the tea gardens, owing to the universal habit of defæcation among the tea bushes, where conditions are entirely favourable to the larvæ. The general index for the upper Brahmaputra Valley is from 200 to 300, and that for the Surma Valley about 300. The hill tribes appear to be nearly free from the infection, with indices of from 80 to 212. These may be safely ignored.

In Bengal the incidence of infection is high, at a general figure of some 80 per cent., but the degree of infestation low, except in the tea gardens of the Dooars and Darjeeling District. In Eastern Bengal the index is as low as 100, in the Sunderbans it sinks to 50. On the Dooars and Darjeeling tea gardens indices of 400 or more are common, and it is clear that hookworm infection is a very important problem for the tea industry in India. (If such a regulation could be enforced, it would seem that the prohibition of

the practice of defæcation among the tea bushes would almost entirely control the infection.)

In Bihar and Orissa the indices are still lower. In the United Provinces and Central India the index of infection in the eastern and northern parts exceeds 200, but gradually decreases towards the South-West. In the Central Provinces indices are from 100 to 110, or even lower. 'The entire north-western part of India (Punjab, Kashmir, North-West Frontier Province, Sind and Rajputana) is for all practical purposes entirely free from hookworm The entire Deccan is practically free from hookworm, nowhere does the index of infection reach 100.'

In South India Mysore is practically free, but in the Western Ghats and Coorg where there are extensive coffee and other plantations, conditions again approximate to those for the Assam and Bengal tea gardens, and indices range from 200 to 300. 'Madras Presidency has within its limits almost every degree of hookworm infection which can be found in India'; in the Deccan the index is practically nil, in the central part of the Presidency it is about 100, in the South Kanara district it exceeds 200, and in Malabar and Southern Travancore it exceeds 300, particularly on the tea estates.

Conditions in the different provinces are next illustrated in a most informative series of 'bar diagrams,' and Dr. Chandler turns next to the information which the survey has collected with regard to helminthic infections other than by the hookworm.

Ascaris and Trichuris infections.—The main source of these infections is drinking water which has been grossly polluted with human fæces containing the ova. Where rainfall is light, or wells protected by raised curbing, and no floods prevail, infections are negligible. On the other hand, in Bengal, Assam, Orissa and some parts of Madras, infections are heavy. In the flooded part of Eastern Bengal during the monsoon two 'islands' were discovered near Gournadi; in one there were 23 households and a single tank so located that contamination from the defæcation areas was unlikely, and here the *Ascaris* infection rate was only 0.7 per cent.; in the other there were over 100 households and a number of drinking water tanks much exposed to infection, and here 80 per cent. of stools examined showed *Ascaris* infection. At Gosaba in the Sunderbans potable water can only be obtained from one tank which is kept carefully guarded and free from gross pollution; here only one *Ascaris* infection was found in 107 examinations.

Where tanks are not the main source of supply of *Ascaris* infections, the latter always appear to be associated with a heavy rainfall. Running rivers are not responsible for much of the disease, but again the tea gardens throughout India suffer heavily. In the Assam Valley, the Dooars, Darjeeling, Wynaad in S. India, *Ascaris* infections range from 60 to 80 per cent. of persons

examined, and may even surpass the latter figure. At Tukvar an incidence of 85 per cent. is recorded. But there appears to be some factor other than contamination of water supplies at work, for in Lower Burma where latrines are in general use, *Ascaris* infections are very prevalent. Flies and dust do not come much into the picture in such areas, and in Northern India where water supplies are often freely exposed to infection *Ascaris* infections are very uncommon or indices low. It would appear that the blazing sunlight of the dry tropical regions of India is extremely inimical to *Ascaris* ova.

In most areas *Trichuris* infection runs parallel to *Ascaris* infection, and only in a very few places was there marked infection with one worm and not with the other. *Trichostrongylus* infection is prevalent in some parts of India, notably Rajputana and the Punjab, and curiously enough appears to affect Mahomedans as much as Hindus, though the association of Hindus with cattle is closer than that of Mahomedans. *Strongyloides* infection was frequently encountered, in spite of the fact that the conditions under which the stools were examined were adverse to the finding of the larvæ; scattered infections were found in Burma, Bengal, Bihar and Orissa, and the eastern Central Provinces. Flukes are relatively unimportant, except—curiously enough—in the Manipur Valley in Assam, where infection with *Fasciolopsis buski* is of frequent occurrence. The infection is also common in pigs in Assam and Bengal, and these animals undoubtedly serve as reservoirs of the infection for man.

Hymenolepis nana.—A curious fact which the report brings out is that this worm is a comparatively common parasite in many parts of India. In the Punjab a 10 per cent. incidence is recorded, in the Central India Agency 18 per cent., and in the Asansol Mining district 28 per cent. The distribution of *Hymenolepis* and of *Ascaris* infections is almost diametrically opposed to one another, but in a few instances dual infection with both parasites has been recorded. On the other hand the distribution of *Hymenolepis nana* infection in India corresponds extremely closely with that of plague, and this brings the strongest possible evidence forward that the dwarf tapeworm of the rat and that of man are one and the same species. *Ascaris* infections are associated with a water supply freely open to pollution with human faeces, *Hymenolepis nana* infections with an abundance of rats living in close proximity to man. *Hymenolepis diminuta*, which is unquestionably primarily a rodent parasite, was encountered in 23 out of 10,000 examinations.

Tania infection is practically absent among Hindus, and rare even among Mahomedans. It was found to be common in only two Indian races, among the Bhutiyas and Tibetans in North India, and among the Shans in Burma. Dr. McDonald of the Charteris Hospital, Kalimpong, records 70 cases of *Tania* infections among 1,400 patients admitted during one year, almost all of

them Bhutiyas and Tibetans. The general infection rate among these castes would appear to be in the neighbourhood of 20 per cent.

Prophylaxis.—The hookworm problem of India is shown in this paper to be of less importance (with the exception of certain districts) than was previously suspected. Nevertheless prophylactic measures are both advisable and necessary. What should these be?

One cannot prevent promiscuous soil pollution in India. It will take decades or centuries of education before so fundamental a change can be evolved in the habits of the people. Yet the village ryot who passes his early morning stool on to the surface of a sunbaked field is doing far less harm than is popularly supposed. The fierce heat of the sun will destroy any dysentery bacilli which it may contain, will shrivel up the cysts of *Entamoeba histolytica*, or the ova of *Necator* and *Ascaris*. It is when he seeks some secluded and shady spot near a drinking water supply, or when rain washes the infective stool into such a water supply that danger ensues.

Are *pucca* latrines the solution of the problem? Dr. Chandler seems to doubt it. The closed-in latrine of Europe is not really suitable for Indian conditions; it tends to become fouled, to become obnoxious, in fact to defeat the very object for which it was erected. One has only to inspect the lavatories in Indian railway carriages to realise how readily such latrines are fouled, and how they repel would-be users. The rural people of India do not like closed-in latrines with sides and roof. 'One can hardly blame an Indian for considering the use of a filthy and smelly latrine far less sanitary and desirable than the use of an apparently clean spot in a secluded place out in the open air.'

The introduction of *primitive* latrines, however, does appear to be practicable. Any arrangement which will keep the feet from coming into contact with the ground before, during, and after the act of defæcation will stamp out hookworm infection, or at least very much reduce its incidence. Such a primitive method is already in general use by the people of eastern and central Bengal where the people habitually stand or sit for defæcation on low horizontal branches or on elevated roots of trees, or on bamboos laid across ditches or pits. 'In our opinion the sanitarian cannot do better as a start than encourage these departures from promiscuous soil pollution in the places where they already exist, and by education and exhortation to endeavour to make their use more universal among the children and men as well as the women, and to extend the custom on the borders of the areas where it already exists.' Standing or squatting on infected ground is the one danger; it should be possible to reform the habits of even the Indian village ryot in this matter. And, as a forcible demonstration of what is to be avoided, Dr. Chandler suggests the actual demonstration to village headmen and schoolmasters of hookworm larvæ, extracted from infected soil before

their eyes, and placed under a low power microscope.

Even if this is not possible, selection and modification of defæcation sites can accomplish something. Areas exposed to direct sunlight should be chosen, and not shaded places, or such as are near a drinking water supply. The spreading of a layer of thatch six inches thick over a defæcation site will prevent access of the larvæ to the feet of people standing on it; and it would not be difficult to build a primitive bamboo platform raised six inches above the ground over a defæcation site. Trench and pit latrines, of however primitive a type, should be encouraged, since hookworm larvæ cannot ascend the vertical wall of a trench. Larvæ developing from a stool deposited into a trench two feet deep only rarely reach the edges of the trench. Further, the wearing of footgear—a most important factor in the campaign against hookworm infection—should be encouraged.

Tea estates present a special difficulty, and here the problem is really serious. The first essential is to prevent defæcation in the area planted with tea. When latrines are erected, special care should be taken to see that they do not become foul or smelly, otherwise money spent on them is largely money wasted.

'If sanitary improvements can be developed to prevent reinfection' writes Dr. Chandler, 'clinical improvement will be rapid even if no treatments are given. We have strong experimental and epidemiological evidence for the belief that hookworms harboured are rapidly reduced in number in the absence of re-infections, and we think that within a year all but the most severe infections would be reduced to a practically harmless level, and that most of the moderate infections would reach this point in six months. We have already shown that an annual dry season extending over four to six months has very much the same effect on the hookworm intensity in a community as has a successful treatment campaign. Nevertheless, mass treatments given during the time that sanitary improvements are being established would unquestionably hasten the beneficial effects, and where practicable they are worthy of consideration.'

On the tea gardens in Sylhet the approximate index of infection is about 300. In this area Dr. Rice carried out mass treatments in two gardens during the hot weather, and Dr. Chandler investigated the results fifteen months later. On Terapassa garden two treatments had been given, one fifteen months previously, the second three months previously; here the index of infection was found to be 59. On Langla garden only one treatment had been given, fifteen months previously; here the index of infection was found to be 98. 'From an examination of these figures' writes Dr. Chandler, 'we are forced to the conclusion that, once having reduced the degree of hookworm infection to a low level by mass treatment, it is not necessary to repeat these each

year, but new arrivals should be treated of course.'

In connection with mass treatment the time of year when these should be given is very important. They should be given in the middle of the dry weather when the heat of the sun will destroy any ova passed. If they are given during the rainy season they may actually make the condition of the soil more infested than ever, and assist re-infections. Unless the results are wanted for scientific publication, it is hardly necessary to examine the stools of all coolies beforehand, and to treat only those who are affected; in all probability about 90 per cent. of the coolies on a tea garden will be infected, and the labour involved in sorting out the non-infected 10 per cent is not worth while; all should be treated. Before the dose is given to each cooly, a cursory rapid examination will serve to sort out those who appear to be in too poor health to be treated. The treatment should be given as far away from pay day as possible, in order to minimise the chances of complications due to alcohol. The best routine treatment, probably, is a combination of 45 minims of carbon tetrachloride with 15 minims of oil of chenopodium, the chenopodium being given in hard gelatine capsules, and the carbon tetrachloride in about half an ounce of saturated solution of magnesium sulphate, diluted with water if desired, both at the same time. This affects *Ascaris* infection also, and although a little more expensive than the treatment with carbon tetrachloride alone, is both more effective and safer than the latter. The treatment should be given about three hours after a meal, which should be as nearly fat-free as possible. Ordinarily, the coolies can return to work on the following day, and not more than half a day's labour need be lost.

* * * * *

Dr. Chandler's paper marks an important step forward in our knowledge with regard to hookworm infection in India. It corrects our previous conceptions as to the virulence of the infection in this country, and almost brings the hookworm problem within manageable bounds; it points out the important areas, especially the tea and coffee plantations in Assam, Bengal, and South India. Accompanying his paper is an extremely instructive map, showing the distribution of hookworm infection with regard to its intensity in India and Burma.

SPECIAL ARTICLE.

MEDICAL RELIEF IN VILLAGES.

By A. HOOTON, C.I.E.,
MAJOR-GENERAL, I.M.S.,
Kasauli.

THE question of medical relief in rural areas has always been one of great difficulty in India, where the population is scattered over immense

areas which in many cases are only thinly inhabited. It is, of course, generally admitted that the most satisfactory way of dealing with the problem would be to multiply indefinitely the regular hospitals and dispensaries, and induce fully qualified independent practitioners to settle in large numbers in the country, but under present conditions, financial and other, this does not appear to be practicable. Local Governments are already complaining of the heavy expenditure entailed by the existing medical organisations, and experience has shown that independent practitioners are not likely to be forthcoming for work in the smaller towns and villages. We are therefore, it seems to me, faced with the necessity of finding some other agency if adequate provision is to be made for the smaller communities.

A scheme for utilising primary schoolmasters, with some elementary medical and surgical training, for rural medical relief, has now been in operation in the Bombay Presidency for about three years, and has met with considerable success, and it may be of interest if I place on record here the considerations which led up to this project, together with some details of its working. The present position with regard to our regular medical men is somewhat anomalous. While the proportion of registered practitioners to the population of India is extremely small—it is said to be 1 to 45,000, as contrasted with 1 to 2,000 in England—there is, in the Bombay Presidency at least, an actual surplus in the places where they are willing to settle. Recently in the Surgeon General's office there was a waiting list of 100 graduate and 139 non-graduate medical men for Government appointments, and anyone who will take the trouble to enquire in Bombay, or the district head-quarter towns, or any of the larger centres, will find that there is an almost unanimous opinion that the number of doctors exceeds the demand. The reason for this is two-fold. Men of the class who are now joining the regular medical profession desire social amenities and schooling for their children which are not available in the villages, and they expect larger fees than the majority of the country people are able to pay. It seems clear, then, that even if the regular practitioners were willing to settle in rural areas they are too expensive; and if this is so it is reasonable to argue that some different and less costly agency is desirable.

POSSIBLE ALTERNATIVE SCHEMES.

Many suggestions have been made at various times with a view to remedying this state of things.

(a) At one time the old Subordinate Medical Service met the requirements, to some extent. They were originally trained in the vernacular for only a short period, and belonging, as they did, to a comparatively humble section of society, were content with low salaries and small fees. This non-graduate class has now, however, been improved to such an extent that the best of them are little if at all inferior to the graduates for

practical purposes. Many of them are drawn from the same social strata as the graduates, and demand similar fees, and they are no more willing to settle in villages, except in Government employ, than the graduates. Thus, they do not now meet the case, and to shorten their training would be a very retrograde step. On the contrary, it is hoped shortly to improve it.

(b) Travelling dispensaries have been advocated in some quarters, but so far as my information goes, these are generally recognised to be expensive and inefficient, except under very special conditions.

(c) It has been suggested that a new class of medical man should be instituted with a comparatively short training in English, or in the vernacular, to replace the old subordinate class, but I consider it would not be wise to confer a regular certificate to practise medicine and surgery on a half trained man of this description.

(d) The employment of compounders, trained in English as they are, has been suggested, but that again is open to objection. The prescribing compounder has always been regarded with aversion by regular practitioners, and I think with reason. He is likely to pose as a doctor, and attempt medical procedures beyond his capacity, and may thus be a danger to the public. Compounders also at the present time demand a comparatively high salary, and if they are properly trained deserve it.

(e) It has also been proposed to recognise the *vaidyas* and other indigenous practitioners. This is a controversial subject which I do not propose to enter on fully at the moment, but much as I admire the work of the old Indian pioneers, such as Charaka and Susruta, I think that we would do well to pause before we perpetuate theories and practice which will not stand criticism in the light of modern science. It is worth while, perhaps, to quote the experience of the Japanese in this connection. At the beginning of their present period of development on modern scientific lines they were faced with much the same problem in relation to their ancient medical system, which was derived from China, and no doubt embodies much matter of interest from the old Chinese writings; but I am informed on good authority that the vast majority of the people have now adopted modern medicine, and that the older system has practically ceased to exist.

The difficulty is to find a method which would not involve the creation of large numbers of medical men of an inferior order. We have the public, as well as our existing practitioners, to safeguard. The present training of our medical students is admittedly none too thorough, and it would be a disaster if any easy back-door to medicine were thrown open.

This objection, however, would perhaps not apply to a distinct class of "village aid" men, trained to render elementary relief in places where no medical men are ordinarily available. My original idea was to take a selected Civil Hospital in each of the 4 chief language areas of the Presidency,

and train 4 or 5 of these men in each, as a beginning. They were to be selected from the villages chosen, as far as possible, and taught, in the vernacular, elementary anatomy and physiology such as is now taken up in many schools, elementary compounding with regard to perhaps a dozen drugs, rough ideas of hygiene (ventilation, clean water, prevention of malaria, etc.), recognition of and simple remedies for the most important diseases, and first-aid work, including the dressing of wounds and ulcers, and what is practicable with regard to eye diseases. Special attention was to be devoted to teaching them to recognise diseases, such as cataract, which, while not suitable for treatment by them, would stand to benefit by a visit to the nearest hospital, and in this way village aid posts should serve as feeders for existing institutions. The men were to work in the wards and out-patient department, the course being made as practical as possible. When trained, they were to go to their villages, and it was proposed to offer a free house and a small retaining fee as an inducement to them to reside there permanently, and to look after the poor gratuitously. As regards persons who could afford to pay, it was intended that the "Upacharak" (i.e., aid man), should be allowed to charge small fees, in order to supplement his allowance.

Practitioners without regular medical qualifications have always been regarded with suspicion, and it is necessary to move with caution in proposing a measure of this kind. In the first place it was desirable to know what view the regular medical profession would be inclined to take with regard to it. I spoke to many representative doctors and was glad to find that the great majority endorsed the proposal, and saw no harm in it from the professional standpoint. This came as no surprise, for the profession has always been broad-minded on large issues, where it considers the good of the public to be concerned. Apart from this, however there were certain instances which could be quoted as forming in some measure a precedent for these proposals. The nurses of the Infant Welfare Centres in Bombay and elsewhere are doing work almost identical with that sketched above, lay missionaries are trained for a few months at some of the English hospitals, with similar ends in view, and as regards eye diseases, the Inspectors of Mr. Henderson's Blind Relief Association (a private association started by Mr. C. G. Henderson, i.c.s.), are covering the ophthalmic part of the programme in Bijapur and Gujarat. Finally, I am informed by a veterinary officer of great experience that it is proposed in one province to revive the old *salutari* class, for village veterinary work, and that he personally is in favour of a quite short vernacular training, for two reasons. In the first place, for economy, and in the second to emphasise the distinction between the *salutari* and the practitioner with a complete training and regular qualification. The Veterinary Department appears to be faced with very much the same

problem as ours, and there is much evidence to show that the humble partly trained man known from long ago as a *salutari* is a very useful individual.

THE VILLAGE AID SCHEME.

For these reasons I am still of opinion that my original proposal was quite sound and practicable, but it met with opposition in various quarters, and we eventually decided to utilise primary schoolmasters, instead of creating a new class of whole-time men.

The adoption of this modification has solved several difficulties. It is even more economical than the original scheme, provides an educated personnel, does away with the contention, which has been frequently brought forward, that a special class of men would not have enough to do, or be able to make an adequate living, and also meets the objection, which was raised by a certain number of medical men, to the creation of a new category of half trained people who might pose as doctors.

The project having passed the Legislative Council, arrangements were made to train five schoolmasters at the Poona, and five at the Bijapur Civil Hospital, as a commencement. A Sub-Assistant Surgeon on the staff of each hospital was given a special allowance of Rs. 25 a month, and Red Cross diagrams and models were provided, together with the St. John's Ambulance and other literature, the special cupboard and equipment which each "Upacharak" is furnished with splints, dressings and a skeleton for demonstration purposes. A simple vernacular manual, covering most of the ground, has also been compiled. The Collectors of Poona and Bijapur, both of whom were favourable to the scheme, were each asked to select, in consultation with their District Local Boards and the educational authorities, five villages of about 1,000 to 1,500 inhabitants, within easy reach of head-quarters (for convenience of inspection), the headmasters of the primary schools in which were willing and considered suitable to undergo training for 2½ months at the respective civil hospitals, on the terms offered. Schools were chosen in which there were two or more masters. During training each master drew a proportion of his salary in addition to the training allowance of Rs. 15 a month, and it was found that an allowance of Rs. 10 a month to the trained man for village work was sufficiently attractive to bring forward volunteers. During training free quarters were provided as near the hospital as possible. The Director of Public Instruction emphasised the desirability of taking headmasters, and not their juniors, and thought, as regards the work in the villages, that arrangements should be made to hold school at mid-day, when this was not already the practice, so that the medical work could be done in the morning. Thus, school might be from 11 a.m. to 5 p.m. (with any necessary break) and medical work from 7 to 8 a.m., subject to modifications corresponding to local conditions and the different seasons.

A large medicine cupboard and dressing table, with simple dressings, and a receptacle for water and waste bucket are provided. The drugs are of course of the most elementary description and few in number, only about 16 preparations being supplied for both internal and external use. Similarly, the appliances consist only of a spring forceps and scissors, with bowls, dressing trays, measure glasses, and a spatula. For internal use the preparations are restricted as far as possible to tablets and pills, so that hardly anything of the nature of dispensing is required. The work is carried on in the school-room, before or after school hours, thus avoiding the necessity of providing a special building. The object aimed at is to enable the masters to do the kind of work that is being done, apart from duties more strictly pertaining to a nurse, by nurses at the Infant Welfare Centres in Bombay, viz., to recognise some of the more important diseases and administer simple remedies, to dress wounds and ulcers and to treat conjunctivitis. They are also given some idea of what is generally known as first aid work, and taught the main principles of hygiene. They are instructed to send cases which they are not capable of dealing with themselves to the nearest hospital or dispensary. Incidentally, of course, they form a very useful agency for the distribution of quinine.

The estimated total cost of training one master (assuming all the candidates pass the practical examination which is held at the end of the course) is Rs. 72, and the maintenance of a trained master in the village, inclusive of a moderate supply of drugs and his allowance of Rs. 10 and dressings comes to Rs. 300 a year. The period of 2½ months has been fixed so that four batches can be trained in a year. Thirty masters have been trained as an experimental measure, and all have now been at work for a considerable period.

The ultimate question of financing this movement, if it reaches any considerable dimensions, has yet to be settled, but it is hoped to interest local bodies, and in particular the District Local Boards and village authorities, so that they may contribute. The control would also, presumably, be eventually in the hands of local bodies, which would no doubt welcome the co-operation and advice of the various district authorities, more especially those of the revenue, educational and medical departments. We have fortunately had the most cordial support and co-operation of the Educational Department throughout, and the movement owes a great deal to the advice and assistance of Mr. Pendarves Lory, Director of Public Instruction in the Bombay Presidency. The only serious departmental difficulty which has arisen is the question of transfer of trained masters, which sometimes becomes necessary in their own interests, or for service reasons, but that is capable of being overcome by having a few trained men in reserve, and putting up for the course only those who are of such seniority as to be likely to remain for some time in places where village aid posts have been established.

In conclusion, to give an idea of the progress of the scheme, the following article, which appeared in the *Indian Daily Mail* of the 8th June, 1927, may be quoted.

"VILLAGE AID SCHEME."

The system of "Upacharaks" Helping Country-Folk Found Successful.

"About three years ago the Government of Bombay introduced a scheme for the medical relief of the rural areas, which is now known as the 'Village Aid Scheme.' Arrangements were made in the Civil Hospitals at Poona and Bijapur for the training of primary schoolmasters in elementary medicine and surgery on 'First Aid' lines and as a result thirty of them were established in villages of about 1,000 to 1,500 inhabitants in the Districts of Poona, Bijapur, Sholapur and Dharwar, where, in addition to school duties, under the designation of 'Upacharaks' they have been giving help to villagers in minor ailments, sending on cases which they are unable to deal with to the nearest regular dispensary or hospital.

The Surgeon-General has now reported on the scheme and states that on the testimony of both officials and non-officials its working has been successful. The 'Upacharaks' have during a period of 16 months dealt with 22,992 cases in Poona, 54,799 in Bijapur, 19,573 in Sholapur and 23,897 in Dharwar Districts. Commenting on their work the Civil Surgeon, Bijapur, observes:—'I have carefully inspected their work from time to time and I feel thoroughly convinced of the utility of these small aid posts in rendering help to our poor ryots, who now willingly seek medical aid from them. It is now a common sight to see clean dressings applied to the wounds of these villagers in place of the usual dirty rags, leaves, feathers, etc.' The opinions of other officers including Collectors and Civil Surgeons and non-officials like Presidents of Local Boards and Municipalities are in the same strain. The scheme has doubtless some obvious limitations and, as the Surgeon-General says:—'It is only suitable for villages of moderate size and the men can only deal with work of an elementary nature, but nine-tenths of the work of a regular dispensary is also of an elementary character. They can dress wounds and ulcers, use simple lotions for conjunctivitis and ear discharges, treat skin diseases, do what is ordinarily known as first-aid work, and administer simple remedies such as quinine, astringents and purgatives. In addition, they may be useful in village sanitation. They may disinfect wells, and, as will be seen from one of the reports, induce the villagers to adopt simple measures of cleanliness. In many ways they will be very useful men in places where there is no regular medical practitioner available, and the cases they cannot treat themselves can be advised to go to hospital. In this way village posts serve as feeders to the civil hospitals.'

The scheme was initiated as an experiment with a view to see whether, if such facilities for medical treatment were made available for them, the villagers would take advantage of them. The results so far reported by the District Officers and others who have had opportunities of watching the work of these 'Upacharaks' have proved that the villagers readily take advantage of the facilities offered to them by this scheme. It is hoped that if the scheme can be further developed as funds become available, it may help to solve the most difficult problem with which the Medical Department has always been faced, viz., the problem of establishing a system of medical relief in the villages at a reasonable cost. Hitherto the difficulty of inducing qualified doctors to practise in the villages owing to the unremunerative nature of such practice, and the heavy cost of opening and maintaining a large number of dispensaries, seemed to make this problem insuperable. The results so far achieved by this village aid scheme afford ground for hope that by the treatment of the simpler ailments, affording first aid in case of accidents and inculcating the elements of sanitation in the minds of the villagers, the 'Upacharaks' may do a great deal towards solving it."

A Mirror of Hospital Practice.

AN UNUSUAL CASE.

By J. L. LUNHAM,

LIEUT.-COL., I.M.S.,

Civil Surgeon, Dharwar.

C. F., aged six, female, English, was admitted on 7th December, 1927, with a history of having swallowed and passed a large piece of glass the previous day. The description of the piece of glass was such that it is almost incredible that so large a piece could, in the first place, have been swallowed, and, if swallowed, that it could have been passed. A sketch of the piece of glass, made by the nurse in charge of the child, is shown and had sharp edges, A—C and B—C. After swallowing this porridge had been given followed by castor oil. A few hours later the piece of glass was passed. Profuse hæmorrhage set in and the child was put in a motor taxi and brought 110 miles by night, arriving at my bungalow at 5 a.m. on 7th December, 1927. During the journey there

had been four attacks of hæmorrhage. The nurse stated that in all about three pints of blood had been passed. This must have been an exaggeration.

On examination, the child was somewhat collapsed. The abdomen was soft. Slight tenderness was complained of to the left of and below the umbilicus; $\frac{1}{4}$ gr. of morphia was injected, and the patient taken to the Civil Hospital. Before arrival there were four more hæmorrhages, each about a teaspoonful of bright blood.

Rectal examination showed no sign of a cut. Intravenous glucose and saline was given. A slight hæmorrhage took place and after this all bleeding ceased. About mid day collapse set in. It was thought at one time that the child was dead, but artificial respiration brought her round. She remained conscious but in a very weak state for the rest of the day. Early next morning she developed a typical tetanic spasm. Opisthotonus and lockjaw were well marked. A small septic sore was found on the right foot. The temperature rose to 106°F . The child was packed in ice, 1,500 units anti-tetanic serum injected, and chloral given per rectum. The following morning lumbar puncture was done. The fluid was under very high pressure and about 25 c.cms. were allowed to escape. 1,500 units serum were injected into the spinal canal. Lumbar puncture and injection of serum was performed in all four times and each time the fluid was under high pressure. It remained clear throughout. The blood was examined on three successive days for malaria with negative result. On the fourth occasion a slide examined in the Civil Hospital was negative, but another slide, sent for examination elsewhere, was reported to contain malignant malaria parasites. Acting on this quinine, intravenous and intramuscular, was given in large doses. Quinine had previously been given per rectum. Another doctor, one of large experience, who also examined this slide, failed to find any parasites so the question of malaria is a doubtful one.

The spasms persisted throughout the whole course of the disease. They were difficult to control and were more marked when the temperature began to rise. Morphia seemed to be the only drug to have any effect. Opisthotonus was always well marked. Sometimes there was tremor of the arms and legs. The leg on which the septic sore was situated was always more rigid than the other. The lockjaw passed away almost entirely on the third day. The abdomen remained soft, luckily, as otherwise laparotomy might have been done, as was indeed advised.

Packing in ice, sponging and iced enemata were employed to control the temperature. What it might have risen to without these, is difficult to say.

The urine was normal; Kernig's sign was absent; the head was not retracted except during the spasms.

On the fifth day the child passed per rectum a quantity of sloughs, evidently from the cuts along the intestine. She remained more or less unconscious the whole time, but could be fed to a certain extent through the mouth. The fatal termination was ushered in by a temperature of

S. No.	Out-door Rgr. No.	Name of patient.	Age.	Sex.	Size of goitre.	No. of injections given.	Total quantity of sodium iodide given.	Result of observation after 1st month.	Result of observation after 2½ months.	Result of observation after 6 months.	REMARKS.

A CASE OF IDENTICAL DELIRIUM IN REPEATED ATTACKS OF BLACK-WATER FEVER AT LONG INTERVALS.

By RONALD SENIOR-WHITE,
Malariaologist, Bengal Nagpur Railway.

C. F. H., Civil Engineer, first came to the tropics in 1901. For the first two years of his residence in Africa he had no malaria, but in 1903, after a visit to Portuguese East Africa, he developed blackwater fever on his return to Johannesburg. At that time his work on the

Rand Mines consisted in the erection of barracks for Chinese labour, and about two months before his attack, and before his visit to Portuguese East Africa, he had had some professional trouble in connection with the erection of these barracks, inasmuch as the gusset plates—small pieces of angle iron—which were all supposed to be interchangeable, proved not to be so, and the work was therefore troublesome beyond necessity. He states that the trouble over these plates neither imperilled his post nor did the worry rob him of sleep, but during the delirium he was occupied mentally in counting these plates into a heap, moving them from left to right; having made the stack, he then got the idea that all this was all wrong, and re-stacked them from right to left.

After the blackwater attack he was invalided home. Subsequently he came to India, and had malaria badly between 1907 and 1915 becoming a chronic relapser, but thereafter this condition improved, and he describes himself as having become 'acclimatized.'

In September 1926, he was on survey in Mayurbhanj State, in Orissa, and for at least twelve months previously had had nothing to do with gusset plates or construction work at all, though he states that after the first attack the work he had been engaged on had constantly involved the use of such. A week after his return

to Calcutta he again developed blackwater fever, and he states that during this attack he experienced delirium absolutely identical with that of his primary attack twenty-three years previously with the same delusion of counting gusset plates.

The recurrence of the delusion after such a long interval, and especially after twelve months' employment on totally different duties is interesting.

TWO CASES OF RENAL TUMOUR IN YOUNG CHILDREN.

By MRS. SATYAPRIYA MOZUMDAR, M.B. (Cal.),
L.R.C.P., M.R.C.S., F.R.C.S. (Eng.), L.M. (Dub.),
Hon. Surgeon, Barh Hospital, Dist. Patna.

Case No. 1.—A little girl, about 6 years old, was brought into the hospital complaining only of a large growth in the abdomen. Subjective symptoms were none, except those due to the size of the growth; there was no hæmaturia or pain. The duration given was two years. On examination the growth was found to be occupying more than half of the abdomen on the left side and protruding about 2 inches in front. The mass was irregular in outline and semi-solid in consistency. Considering the age and sex of the child, along with the physical signs, it was thought to be a case of congenital polycystic kidney.

An operation of nephrectomy was decided upon as the tumour was hampering intestinal and respiratory movements; presumably the other kidney was working as the child was otherwise healthy.

On operation, by a prolonged transverse incision, it was found to be a hypernephroma, the typical, yellowish-red soft growth being situated on top of a quite healthy-looking but a slightly enlarged kidney. The tumour was encapsulated almost entirely except at its inner margin, where it invaded the region of the aorta and lumbar glands. Probably the growth was completely encapsulated and innocent at first, when it was slow-growing, but recently, according to the history, it had suddenly increased in size, and had apparently become malignant. It went beyond the middle line and partially surrounded the aorta and the large veins there.

The kidney itself, though healthy to look at, had to be sacrificed along with the tumour for fear of recurrence, but unfortunately it was found towards the end that some parts of the growth had to be left behind where it had encroached on the aorta and big veins. The child stood the shock of the operation well and made a good recovery except for a stitch sinus which healed quickly on removal of the stitch. But during convalescence, a peculiar symptom appeared. Large patches of alopecia areata appeared on the head, suggesting some disturbance of internal secretion. She was put on thyroid extract and calcium lactate, and at the end of three months, when I saw her again, the hair had

started growing. The pathologist's report confirmed the diagnosis of hypernephroma. Although 3 months after the operation, the child had put on fat and was quite healthy to all appearance, I am not at all satisfied that recurrence will not take place. Unfortunately, though asked to report at the hospital once every month, she has not turned up yet. I am trying to make enquiries about her condition through the local thana.

Case No. 2.—A boy about 10 years was brought in with a large cystic growth in the abdomen, with the history that he fell from a tree about a fortnight before and had developed this swelling since. The size and tenseness of the abdomen was such that it was impossible to believe that statement. It was the size of a large ovarian cyst, and, if the patient had not been a boy, one would certainly have thought of an ovarian in this case.

On examination a uniform tense swelling was found filling the entire abdomen, with a distinct thrill. But beyond the fact that it appeared to be a unilocular cyst one could not venture on any diagnosis, in the absence of any symptom whatever, except the mechanical discomfort from it. The apex of the swelling was in the middle line about the umbilicus so that there was nothing to indicate that it was not an intraperitoneal growth.

But to my surprise, on opening the abdomen in the middle line, it was found to be a retro-peritoneal growth coming from the right kidney region. So an incision was made through the posterior peritoneum, and the cyst being so enormous that it could not be brought out of the wound it was tapped. As expected, it was an unilocular cyst with a thin fluid which had a very large admixture of blood. Unfortunately, a specimen of the fluid was not kept for examination but it was not mucoid, nor had it any urinary odour.

What puzzled me was, what was this cyst? The wall of the cyst was very thick and smooth, there was no trace of any kidney substance. It was smooth inside and out. That it could not have been of a fortnight's duration only, was perfectly clear. But there was the definite history of a fall from a tree and noticing of the swelling since then.

I fancy that the cyst must have been there at least a year before, but it did not produce any symptoms to have attracted the attention of the patient. It is probable that the fall from the tree led to sudden hæmorrhage and consequent enlargement of the swelling, and that this was enough to draw attention to it.

The diagnosis lay between a hydronephrosis (congenital or acquired) and one of that rare condition, solitary cyst of the kidney. From the naked eye appearance, it could easily have been either; and as the ureter could not be reached during operation, nor could it be examined after death, as a post-mortem was

not allowed, the actual diagnosis of it must remain uncertain. The enormous size of the cyst point more to a hydronephrosis than a cyst; but beyond this any speculation is futile.

The sac was excised, except a small portion which had gone beyond the middle line and too far below to be approached. The peritoneal wound was stitched with a drain left through the loin. This drain probably closed too early or was insufficient, for the patient did quite well for 5 to 6 days, after which he developed signs of peritonitis and died on the 12th day. If another drain had been left in the peritoneal cavity, probably peritonitis could have been avoided. But the child had a very poor physique to begin with, and then this large amount of hæmorrhage inside the cyst must have enfeebled him further, so that he could not cope with the strain.

A CASE OF SPONTANEOUS RUPTURE OF ENLARGED SPLEEN.

By G. RAGHUNATHA RAO,

Medical Officer, Leper Asylum, Cuttack.

SPONTANEOUS rupture of enlarged spleen is rather rare. Waddell, in *Lyon's Medical Jurisprudence for India* (6th Edition, 1918) has given a description of three illustrative cases and also mentions that two more cases were published in the *Indian Medical Gazette* of 1904. Therefore, a brief description of the following case which recently occurred in this asylum may be of interest.

B. M., Hindu, male, age 45, a "B3" case of leprosy and an inmate of this asylum had an enlarged spleen which extended down to the left iliac fossa and to the right about 1 inch beyond the umbilicus. The duration of the enlargement was $1\frac{1}{2}$ years. He used to get occasional attacks of fever. His blood was examined on one occasion, and numerous benign tertian gametocytes were found, and also a few trophozoites. He refused to undergo a complete course of treatment with cinchona febrifuge. A quack doctor whom he secretly consulted branded him over the skin of the abdomen in the region of the spleen. For 2 months after branding he was all right.

On 6th December, 1927, at about 6 a.m. he was suddenly seized with a violent pain in the region of the spleen. He had not sustained even the slightest injury, not even straining at stool. He became restless and when I examined him at 7-30 a.m., he had a hæmorrhagic pulse. On inclining to the right side the right flank showed a distinct bulging and a dull note was elicited on percussion. The bulging was found to be due to fluid and not to flatus or fat. He felt great discomfort as the abdomen was gradually distending. At about 11 a.m., he expired. Shortly before death, his abdomen was fully distended and the enlarged spleen, though not fully palpable, could be distinctly felt as if it were floating.

An autopsy in this case would have been valuable, but it could not be done as this asylum is a private institution and there are no facilities for conducting autopsies.

ATROPINE SULPHATE IN A CASE OF STRANGULATED HERNIA.

By P. M. ABRAHAM, L.M.P.,

Forest Tramway Dispensary, Kuriarkutti, Chalakkudi.

I WAS in camp at Chalakkudi on the 10th January, 1928. That evening at about 9-30 p.m. I was called in to attend on a case of strangulated hernia.

History.—Jabar Sahib, a watchman attached to the tramway workshop, aged about 40, used to get intestinal colic now and then due to constipation of a chronic nature; on these occasions he used to get himself cured for the time being.

On the 8th January he got a similar attack and as usual he took an ounce of castor oil with some warm coffee early in the morning next day (9th January). He got only three motions, but not one of them was quite satisfactory, and he began to feel some sort of uneasiness in the right inguinal region where he noticed a slight swelling in addition. By next morning the condition grew worse, the pain in the inguinal region was increasing and the swelling that he noticed on the previous day also increased in size. So he sent word through one of his relations to one of the local doctors who apparently sent a few ounces of mistura alba. The patient took a few doses of the mixture; every time he took the mixture he vomited and the swelling noticed began to increase in size, and so at about 6 p.m. he was taken to the same doctor who tried to reduce the swelling without success, and as a result of that he advised the patient's relations to take him to Trichur. Since there was no convenient train, it being late in the evening and since he was not able to hire a motor vehicle, they were not able to take him then and there. Consequently they had to wait till the next morning (the 11th). In the meantime one of the patient's relations came to me and requested me to have a look at the patient. When I saw the patient, he was rather restless, the abdomen distended, pulse weak and rapid, vomiting present, face pale, tongue furred and eyes a bit sunken. The swelling in the inguinal region and scrotum was about three times the size of a tennis ball. On account of the pain he would not allow me to manipulate the swelling freely. Of course the swelling was of an elongated shape. After examination I told them that in case there was no improvement by next morning he should be taken either to the General Hospital, Ernakulam, or the Civil Hospital, Trichur, the two well-equipped institutions of this State.

After this I gave him an injection of atropine sulphate 1/100 grain hypodermically and advised him to have mild and gentle turpentine fomentations; in addition I got the scrotum raised a bit by a small cushion made for the purpose. I returned from there asking the relatives to let me know the condition by five o'clock in the morning. By morning to everybody's surprise the swelling disappeared; the patient had three good loose motions and he was feeling hungry. During the early morning I went there and put a pressure bandage in the inguinal region and asked him to take complete rest for a week and liquid diet. After this period he began to have his daily routine of work and diet. When I was leaving the station for my headquarters which is some 41 miles away from there I found him quite healthy.

It seems to be well worth while to give a trial to atropine sulphate whenever possible in such cases, as suggested by Captain N. N. Ghosh (vide *Indian Medical Gazette*, December, 1927).

"Poona-itis."

For many years Poona has been notorious for the great prevalence of intestinal disorders in that station during the monsoon, a condition which is generally referred to as "Poona-itis." This matter was the subject of an enquiry by Lieut.-Col. J. Morison in 1913-14, who came to the conclusion that it was impossible to separate out the various intestinal disorders prevalent, either clinically or bacteriologically; all were included under the general term "Poona diarrhoea." It was noted that the prevalence of flies in the station bore a close relationship to the intestinal disorders during the early part of the monsoon, but in August the number of flies dropped rapidly, but not the incidence of intestinal disorders. The diarrhoea was apparently closely related to the rainfall, and was suspected to be due to the contamination of Lake Fife from which the Poona water supply comes.

In 1925 conditions among the troops in Poona were just as bad as ever, and a renewed study of the subject was taken up by Major J. A. Manifold, D.S.O., R.A.M.C. and Military Assistant Surgeon A. J. de Monte, I.M.D. Their report appears in the *Indian Journal of Medical Research* for January, 1928 (Vol. XV, No. 3, p. 601), and is a document of paramount importance to all laboratory workers in this country.

They found on commencing their work that conditions in Poona in 1925 were similar to those in 1913, with the important exception of the water supply. This was unimpeachable; the catchment area around Lake Fife had been well protected, the water was also chlorinated, and on daily bacteriological examination never yielded lactose-fermentors in 100 c.c. Thus, whatever Poona diarrhoea was due to, the water supply could be at once ruled out. The enquiry was unfortunately suddenly interrupted in October, 1926, when Major Manifold was transferred elsewhere, but even the incomplete report, which is given in sections, is of great interest.

The first essential was to secure the co-operation of the officers in charge of the various military hospitals, and this was readily forthcoming; indeed the authors point out the importance of such collaboration; without it the laboratory worker is working in the dark. Every soldier suffering from diarrhoea, of however mild a character, was ordered to report sick; printed instructions were circulated to all medical officers and assistants, also printed case sheets, particulars on which had to be filled in in detail. Sera were collected, fly traps issued, and weekly fly records instituted.

The first and most important finding is that almost all these cases of Poona diarrhoea are due to mild infections with the dysentery bacillus of Flexner. Indeed, it would appear that that bacillus is far more often the cause of diarrhoea than of dysentery. It was also responsible, however, for the greater majority of cases of dysentery in the station. Infections due to the bacillus of Shiga were far less prevalent, but if such patients reported at once, and were immediately put under treatment, the disease might run just as mild a course as in the case of Flexner bacillus infections. With proper co-operation between hospital authorities and the laboratory it was nearly always possible by the microscopic examination of the stools to separate mild bacillary dysentery, with its characteristic cellular exudate, from diarrhoea. Both conditions are present in Poona during all months of the year, but increase markedly during the monsoon period. Amoebic dysentery is a comparatively rare disease among the troops, as contrasted with the great prevalence of bacillary dysentery infections.

With regard to epidemiology, the water supply is in no way responsible. There is a heavy infection among

the Indian population in the cantonment with the bacillus of Flexner, and this is passed on by them to the European population by direct contact, handling of foodstuffs, etc., throughout the year. At certain seasons, especially during the race meetings, the cantonment becomes very crowded and conditions become especially suitable for the transference of the infection. "The existing sanitary arrangements in Poona are absolutely ideal for the spread of bacillary dysentery" write the authors, with unconscious humour. The latrine system is one of open pans, the contents of which are nominally collected by carts twice a day, and remain exposed to the air for the remainder of the 24 hours. The Manick Nullah between the city and cantonment is practically one vast open latrine. During the racing season some 1,200 horses and their syces are accommodated in stables within the cantonment, and the syces scatter the infection further afield. The average for the year of constantly sick from bacillary dysentery was 2.84 per mille for British troops and 1.88 for Indian troops.

Flies were found to be of great importance in the spread of the disease. The curve of fly prevalence runs parallel with that for dysentery and diarrhoea, with a high peak in August, until September, when the number of flies rapidly drops off, largely due to epidemic infection of flies with a fungus, *Empusa musca* in all probability. "Bacillary dysentery" cases, diarrhoea cases, and flies are present in Poona throughout the year, and largely rise and fall together." On 3 occasions out of 8, batches of wild flies caught in the cantonment gave cultures of the bacillus of Flexner from their intestinal contents. The flies pick up the infection from the open latrine pans through the cantonment and from the latrine area of the Manick Nullah and scatter infection with bacillary dysentery throughout the cantonment. Contact infection is also important, and many cases occurred where mothers attending on children suffering from *B. flexner* infections contracted the infection. On a general examination of the sera of troops in the station, no less than 31.8 per cent. of British troops showed agglutinins to the bacillus of Flexner present in significant titre, and 50.6 per cent. of Indian troops. Shiga agglutinins were only found in 3 out of 187 persons examined. One of the chief sources of danger is the bacillary carrier who is in relatively good health, and who does not notice the fact that he constantly passes a slight amount of mucus in his stool.

The second section of the paper is devoted to an analysis of the bacteriological findings. A good description of the technique employed is given; the importance of having the McConkey plates dry before inoculation is emphasised, and the value of Teague and Clurman's glycerine-saline solution for the preservation of dysentery bacilli in stools noted. Agglutinins against the bacillus of Flexner appeared in 72 per cent. of the series of cases tested and in 57 per cent. of "dysentery group" cases also. The agglutinins appeared about the 12th day of the disease and were at highest titre about the 23rd day after the onset of the disease. The severity of the attack bore but little relationship to the production of agglutinins. Agglutinins to the bacillus of Shiga were absent from all Flexner bacillus infections studied, whilst agglutination was strongest against the Flexner V of the five strains examined.

As is well known, and further confirmed in the present paper, many Flexner bacillus strains do not agglutinate with the specific antiserum when first isolated, but acquire the property of agglutinability when sub-cultured. Of 117 strains isolated 71.7 per cent. only were agglutinable to the five Flexner strains after many months of sub-culture. Eight hour readings on the water bath at 55°C. in place of the usual four hour readings, improved and reduced the number of inagglutinable strains by 15 per cent. Only 51 per cent. of agglutinable strains could be suggested to one or other of the five standard Flexner types given in the Medical Research Council Special Report No. 42. Inagglutinability and lack of agglutinogenetic power appear to be closely related to one another. Evidence was found of

at least one strain with apparently no antigenic relationship to the five Flexner strains, and there are probably many others; thus showing how wide a variety of constituent races go to make up the "Flexner bacillus" group of bacteria.

* * * * *

Major Manifold and Assistant Surgeon de Monte are to be congratulated on an exceedingly interesting and important contribution to our knowledge of the dysenteries of India, whilst the indications for sanitary reform in Poona cantonment are obvious.

Quinine-Stovarsol in Benign Tertian Malaria.

IN the January 1928 number of the *Indian Journal of Medical Research*, Major J. A. Sinton, v.c., i.m.s., continues his studies in the treatment of malaria, in conjunction with Major W. Bird, r.a.m.c., and Military Assistant Surgeon S. N. Eate, i.m.d. The tests were carried out on cases of benign tertian malaria among British troops at Kasauli.

Stovarsol, which is stated to be acetyl-oxyamino-phenyl-arsenic acid, was originally prepared by Fournau in 1924, and has now been on the market for some time as a drug for the treatment of and even prophylaxis against syphilis, amœbiasis, relapsing fever, and malaria. In previous studies Major Sinton has shown that it has a markedly destructive action on *Plasmodium vivax*, but that it does not prevent relapses in benign tertian malaria. Hence the suggestion to combine stovarsol with quinine for oral administration, the new compound having been prepared by both the Haco Company of Berne and Messrs. May and Baker, London.

As in his previous work, Major Sinton relied on the diagnosis of "relapses" by finding malaria parasites in thick films of the peripheral blood taken once a week for eight weeks after the cessation of all treatment. The same author has also previously noticed the possible provocative action of stovarsol, when administered by itself and without quinine; daily doses of 1 gramme being liable to provoke a febrile response with appearance of parasites in blood films.

With quinine-stovarsol no toxic action was observed. The authors conclude as follows:—

"Under the conditions of our work (at Kasauli) stovarsol seems to be a useful adjuvant to quinine in the treatment of malaria. The compound quinine-stovarsol does not seem to be more efficacious than the two drugs given simultaneously, but it is more easily administered. It is possible that if larger doses of both quinine and stovarsol were given during the first week of treatment, followed by a course similar to that described in this paper, better results against relapses might be obtained, especially if the amount of quinine was increased."

(Any medical practitioner who has worked in India for a number of years must have been forced to recognise the value of the administration of arsenic, not so much in the direct treatment of a malarial attack, as in the follow-up treatment after quinine therapy. Stovarsol is a most interesting compound. Dobell and Laidlaw have shown experimentally that in amœbiasis it is far less efficient than emetine as an amœbicide, yet it has a distinct value—in the reviewer's experience—in the follow-up treatment of amœbiasis, whether after a course of emetine injections for the treatment of acute and sub-acute amœbic dysentery; or after a course of bismuth emetine iodide in the treatment of chronic amœbic infection. The high content of the drug in organic arsenic which appears to be readily absorbed seems to render it of distinct hæmatinic value, and its real value may perhaps not be due so much to any direct parasiticidal action as to its general value in raising the patient's resistance.)

A Comparative Study of the Action of the Cinchona Alkaloids on the Uterus.

By R. N. CHOPRA,

LIEUT.-COL., I.M.S.,

J. C. DAVID, M.B., B.S.,

and

B. B. DIKSHIT, M.B., B.S., D.P.H.

(*Indian Journ. Med. Res.*, 1928, Vol. XV, No. 3, p. 571.)

THERE has for many years been an impression that quinine, when administered to pregnant women suffering from malaria, may lead to miscarriage. To some extent this is true, although it is far more true that the malaria itself may cause miscarriage, and malaria in pregnant women should be just as thoroughly treated with quinine as in other patients, though dosage may have to be reduced and the treatment proceeded with more gradually.

In this connection the present paper is of special interest, for the authors are clearly inclined to attribute the oxytocic or abortifacient action of quinine to contamination with quinamine. Having experimentally investigated the stimulant action of the different alkaloids of cinchona bark on the uterus of the cat and guinea-pig, they conclude that the uterus of the guinea-pig is more sensitive than that of the cat. The hydrogen-ion concentration of the fluid in which the different alkaloids act may affect results; the cat's uterus works best at a pH of 7.6, and that of the guinea-pig at a pH of 7.2. In general, the dextrorotatory alkaloids have a more powerful effect than the levo-rotatory ones. The most powerful alkaloid of all is quinamine.

Quinamine in dilutions even as high as 1 : 500,000 causes marked tonic contractions of the isolated virgin, pregnant, or multiparous-pregnant uterus; doses of from 2 to 5 mgms. may send this organ into almost spasmodic contraction. With regard to the different cinchona alkaloids hydrocupreidine and hydrocupreine and cinchonine come next, whilst quinine and quinidine come low down on the list. "The oxytocic action of quinine is quite pronounced when the uterus is nearly full-term, but in early cases of pregnancy, beyond slightly increasing the amplitude of the automatic movement, no untoward effect is likely to be produced. This is also borne out by clinical experience." In brief, it is suggested that any abortifacient effect of quinine may be due to its containing a slight amount of quinamine.

Malaria in Coorg.

By T. C. McCOMBIE YOUNG, M.D., D.P.H.,

LIEUT.-COL., I.M.S.,

and

ASST. SURGN. J. D. BAILY, I.M.D.

(*Indian Journ. Med. Res.*, 1928, Vol. XV, No. 3, p. 745.)

IN Southern India, on the top of the Western Ghats, lies Coorg, the smallest Province in British India, with an area of 1,600 square miles. Both its climate and its races are peculiar, whilst it is the seat of an important coffee plantation industry. In 1878 Coorg had a tremendous reputation in the coffee world, for no less than 70,000 acres were under plantation by coffee. In 1883 however a decline commenced, and in 1901 the area under plantation had been reduced to 58,393 acres. In 1917 the coffee industry reached its lowest level, when a further decrease of 24 per cent. was recorded in the area planted. Then a Government loan stepped in and of late years the coffee industry in Coorg has revived to some partial extent.

The population of Coorg reached its maximal figure, 180,607 in 1901; thereafter there was a definite decline. To some extent the influenza pandemic of 1918-19 was responsible for this, but in 1921 the Superintendent reports that this will not account for the whole of the decline. The staple food of the community is rice, the population in general have a fairly high standard of life, conditions are comfortable, and the decline is due to one main cause—malaria. Coorg must be classed as a hyper-endemic malarial area, whilst blackwater fever is also prevalent.

The areas especially investigated in this enquiry were Mercara, the capital of the Province, with a population of 5,600 inhabitants, situated nearly 4,000 feet above sea-level; Verajpet, a municipal area in the southern part; Gonikoppal, a hamlet where a weekly bazaar is held; Somwarpet, a village situated on a high ridge; Fraserpet, a village in the Cauvery Valley; and the coffee estates. The spleen rates found were 55 per cent. for Mercara, 84 per cent. for Verajpet, 79 per cent. for Gonikoppal, 49 per cent. for Somwarpet, 65 per cent. for Fraserpet, whilst the general endemic (parasite) index for the whole Province worked out at 47.6 per cent. Crescent carriers constituted 14.6 per cent. of the total infections. These are clearly conditions under which malaria may be expected to become hyper-endemic, and account for the conditions present.

In order of prevalence, the important anophelines present are *A. listoni*, especially prevalent in open surface drains; *A. maculipalpis*, found in running water and in seepage water and tanks; *A. culicifacies*, found in many different breeding places; *A. minimus*, found in association with *A. maculipalpis*, *A. jeyporiensis*, *A. vagus*, *A. subpictus*, and others. The annual mean relative humidity is about 80 per cent. and the mean monthly minimum temperature does not fall below 56.7°F. The country in brief is one which resembles the Garo Hills in Assam, but appears to be free from kala-azar.

Recommendations.—The report is based upon observations which were carried out over a period of only five weeks, and is therefore but a partial one. Yet it is of special interest in its recommendations. The municipal drains in Mercara are apparently its chief source of *A. listoni* breeding and of its malaria. The wells are quite clear of anopheles larvae and therefore not dangerous. Complete eradication from such a hyper-endemic area cannot be hoped for, but a considerable reduction in its malarial incidence is possible. Propaganda work and the introduction of mosquito nets are urgently called for; the latter especially, seeing that the employees on the coffee estates can well afford nets of cheap pattern. A peculiar feature of Coorg is that for many years after 1862 it was the centre of a cinchona plantation, but by 1902 the cinchona industry in the Province had died out, and has never been revived.

The authors believe that in the revival of cinchona plantations in Coorg lies the chief solution to the malaria problem in that Province. Investigations of recent years have shown that all the cinchona alkaloids are almost equally efficacious in the cure of malaria, and former civil surgeons and officials in Coorg have recommended the cultivation of cinchona. The soil and climate of the Province are eminently suitable; it was once an important centre of cinchona cultivation; in brief, "every inhabitant, his own cinchona tree" would appear to be the best remedy. He can make a decoction of the bark. "Subject to expert advice from those personally conversant with the business of febrifuge production" write the authors, "we would incline to think that the production in Coorg of febrifuge for provincial needs is a proposition which is within the range of practical politics, more especially as its main object would be that of demonstrating how a cheap remedy for malaria could be placed at the disposal of a population, more than half of whom are, to judge from the spleen rates, permanently in need of it."

* * * * *

A most interesting and stimulating paper (though it would have been improved by the publication of a

summary of the findings). Coorg is clearly a hotbed of malaria; yet the Province can grow her own remedy for the conditions present. There must be few areas in the tropics so favourably situated, riddled with malaria, yet eminently favourable for the local output of cinchona febrifuge. Cause, effect, and measure for prevention are all present simultaneously.

The Liver Function in Sprue.

By S. S. SOKHEY, M.D.,

MAJOR, I.M.S.,

S. K. GOKHALE, M.SC.,

M. A. MALANDKAR, M.SC.,

and

H. S. BILLIMORIA, M.B., B.S., D.T.M.,

(*Indian Journ. Med. Res.*, 1928, Vol. XV, No. 3, p. 553.)

It has long been a doctrine that in sprue there is serious impairment of the liver function. Diminution in size of the organ is constantly present in the later stages of the disease, and it has been assumed that, with this diminution, there is grave impairment of liver function.

Major Sokhey and his colleagues have experimentally investigated this theory by laboratory tests at the Haffkine Institute, Bombay, on thirteen cases of the disease. Their conclusion is that hepatic functions are *not* depressed in sprue, except perhaps in its terminal stages, and this finding will surprise many of the orthodox. Their summary of their work is as follows:—

"Thirteen cases of well marked sprue have been studied. Nitrogen partition does not reveal any inefficiency of the liver. The bromsulphalein dye retention test has given negative results, except in one case in which it may well have been due to the extreme lowering of the vitality generally on account of the approaching dissolution—the test was done three days before the patient died. Increase in the serum bilirubin in six cases, as shown by the indirect van den Bergh reaction, indicates increased destruction of erythrocytes rather than defective function of the liver. If the liver had been at fault, the dye test would have shown a parallel retention. Seven cases gave abnormal laevulose tolerance curves, but on account of the non-specific nature of this test, and negative results yielded by the other tests, we cannot interpret our abnormal curves in terms of liver inefficiency. In sprue, inanition may more likely be responsible for the abnormal laevulose tolerance curves rather than the condition of the liver. Our investigation, therefore, shows that in sprue the liver is not affected to such an extent as to show impairment by liver function tests."

The true aetiology of sprue is so mysterious that even a definite negative finding in such an investigation has considerable value in excluding theories as to the causation of the disease.

The Sidney Rowson Wilson Prize.

We are asked by our contemporary, the *British Journal of Anaesthesia*, to publish the following particulars with regard to this prize. It has been instituted in memory of Mr. S. R. Wilson, who died some months ago whilst undergoing certain experimental tests with reference to anaesthetics upon himself.

Competitors should send their reports to the Secretary, the *British Journal of Anaesthesia*, "Ainsdale," Pafatine

Road, Withington, Manchester, England, to be received before December the 1st, 1928.

As announced in the January number of the *British Journal of Anaesthesia*, for the best Inhalation Anaesthesia Research Effort, worthy of a premium, carried out by a citizen of the British Empire between the present date and December 1st, 1928, a prize of Fifty Pounds is offered.

Every competitor is expected to conform to the following regulations:—

(1) To forward to the Secretary of *British Journal of Anaesthesia*, on or before the first day of December, 1928, a typewritten report of his or her work, in triplicate, with a *nom de plume* thereon, and also accompanying same a sealed envelope having the same *nom de plume* inscribed on the outside and his or her name and address within.

(2) All competitors assign to the *British Journal of Anaesthesia* all rights of publication.

(3) The *British Journal of Anaesthesia* reserves the right to decide if any effort received is of a sufficiently high grade to warrant the award.

Reviews.

ABRIDGED REPORT ON MALARIA IN THE ASSAM TEA GARDENS.—By C. Strickland and K. L. Chaudhury. Published by the Indian Tea Association.

THE first quarrel that one has with this publication is that it is 'abridged.' This is not the fault of the authors, but of the Indian Tea Association. This is the more extraordinary when one considers the excellent style of the Association's series of scientific reports, dealing with the agricultural problems of the industry, and makes one imagine that in their eyes diseases of their product are more important than diseases of their producers. Consequently, wherever the authors' meaning appears obscure, the reviewer must always feel that the omission of important tables and charts must be heavily allowed for.

The second quarrel is likewise perhaps captious. The authors are writing for those engaged in the tea industry more than for their scientific brethren, but unless the latter are fully conversant with the topography and vernaculars of the tea area, much must remain obscure that otherwise would have been helpfully explained in a preliminary chapter dealing with the terrain surveyed, and hence the value of the report to those engaged on similar work elsewhere is correspondingly lessened. None the less the report is full of interest to the practical malariologist.

However, there are many apparently contradictory statements which the authors might easily have elucidated. For instance, though they mention the futility of ascribing to a garden the spleen-rate of recently imported children, and state that until two years' residence has been achieved this index is not representative of the results of local residence, yet their table on page 7 seems to bring out the fact, most important if true, that over a large number of imported as against garden-born children the rates are practically equal, presumably irrespective of length of residence in the former. Similarly, after reading that there is a very fair correspondence between a garden's local reputation for 'malariousness,' and its actual spleen-rate, one recollects the directly contradictory statement on the preceding page that there is no relationship between these facts.

Again, on pages 89-90 there are apparently contradictory statements regarding the harmlessness of *khet* land, whilst the last two lines and the footnote on the former page directly contradict one another without a further explanation being added to the footnote. Similarly, the caption to fig. 13 and the first line on page 107 opposite are directly contradictory. Discrepancies such as these can hardly fail to impress most unfavourably the practical man who will study the report. Certain it is that such apparent contradictions are always being discovered in scientific work, but when writing a report of this nature the reviewer considers that it is essential to constantly bear in mind the fact that those for whom it is written are not scientists, but do expect the scientists they employ to report clearly in terms intelligible to them. The report loses most of its practical value owing to these discrepancies.

From the scientific view-point, however, there is much of interest. The discussion on pp. 10-14 on carrier species is good, but the total list of Assam Anophelines should have been included here, instead of in part III, where it can only be found as a table in the contents page of that section. The decision to proceed on the assumption "once a carrier, always a carrier" is sound practically, however much one may regret the present unsatisfactory evidence against many species so ably summarized recently by Covell. None the less, the reviewer does not altogether understand the attitude taken up by the authors in regard to their practice of 'lumping' several species together for tabulation purposes. Nothing, in his opinion, could be more fatal to practical results than the lumping (as illustrated on p. 15) of *culicifacies* with *rossi* and *vagus*. The two latter can be neglected everywhere, the former is one of the worst carriers in India. Nor is the necessity for this apparent. It is only the veriest tyro, or a most careless worker, who will fail to separate *culicifacies* and *vagus* (we agree with the authors that true *rossi* is probably absent from Assam). Either the staff employed could identify, or they could not. From the comments on p. 17 one gathers that the staff were not altogether satisfactory, but unless trust can be put in their capacity to carry out plain scientific diagnosis, the survey should never have been put through, for one table on p. 16 shows that 40 per cent. of the total catch consisted of this eminently unsatisfactory mix-up of species. Similarly so in the case of *sinensis* and *barbirostris*. In regard to the latter there is, to our mind, as yet no justification for implicating it as a practical carrier species, with all the particularly difficult control problems that this envisages. It is admittedly associated with *funestus*, and when in company with the latter can be attacked *pari passu*, but breeding when not so associated in our opinion can be neglected. The authors agree with the reviewer as the negligibility of *fuliginosus*, a far more commonly condemned species than *barbirostris*. On p. 92 *karwari* is given as a reputed carrier. On whose authority? We have always followed Hacker, who alone seems to have investigated the point, in neglecting it.

The authors find that there is no apparent operation of what Christophers and Covell have called the 'economic factor' in the malaria causation of tea gardens. This is in accordance with the reviewer's experience, and only indicates how the yet-to-be-made attempt to control malaria among a truly rural population where this factor operates is going to be more difficult than any attempt so far made in India.

A very interesting point, deeply affecting all large scale survey work, is whether there is much seasonal fluctuation in the spleen-rate in hyper-endemic areas. The authors think not, but it appears by no means certain by whom the rates were taken. On p. 79 the footnote throws doubt on the accuracy of some such. To be comparable, spleen-rates are emphatically a job for a few thoroughly trained observers, not under any circumstances for Sub-Assistant Surgeons without special training.

This is admittedly a general survey, but it is full of remarks showing how futile it would be to base any

practical work or expenditure on generalities. Whilst we agree with the dictum that the smaller the stream the more is its malarious potentiality, this is to some extent contradicted by the fact that a very small stream probably dries off very quickly. The authors state that their knowledge is deficient on such points.

Nothing is said concerning the length of the transmission period in the various parts of the area surveyed, and yet there are probably enough meteorological records available to generalize. It may be that the smallest and most dangerous streams only flow during the transmission period, in which case they could in any case be neglected during the rest of the year; it may be that the transmission period extends over nearly all the year in which case the life of streams and wet weather swamps could only mark exacerbations in the general intensity of transmission. Meteorological factors of this nature could well have been added to the descriptive preliminary chapter that we have shown to be such a desideratum.

The remarks on siting habitations are applicable, not only to the tea garden, but to every industrial undertaking throughout the East. The unfortunate sanitarian is invariably invited to do his best to rectify the mistakes of those of other professions who have made decisions outside their proper domain.

On p. 114 the astounding remark is made that sub-soil drainage is not 'practical politics' in Assam. May we ask why? Who said so, the malariologist on technical, or the planter and his managing agents on financial grounds? Photo after photo in the report shows sites where subsoiling would certainly appear to be a practical solution. Perhaps the 'crabsticks and mugwumps' referred to in part VII have made the decision!

Finally, we concur with the authors that better medical statistics, and a card-index of the medical state of each coolie should be prepared and kept in future. Half the financial loss caused by disease is not appreciated through the inability of the medical profession to furnish statistics, and in any case, be it whispered, to the general dislike of that profession to the handling of such.

R. S.-W.

CHRONIC CONSTIPATION.—By J. Ellis Barker. London: John Murray, Albermarle St., W., 1927. Pp. 503. Price, 7s. 6d.

This book is really a presentation of the teaching of Sir W. Arbuthnot Lane. It presents a 'gruesome' picture of the evil effects of intestinal stasis caused by unsuitable diet. The book consists very largely of selected extracts from the works of well known authorities, and regarded as a case "for the prosecution" it must be regarded as very complete and damaging. There are over-statements which create an unfavourable impression, for example "where constipation is universal, pyorrhoea, tonsillitis, and cancer of the stomach and bowel are also universal."

Again there is a statement which ought to be greatly qualified. "Disease is caused not so much by certain micro-organisms as by the weakening of our tissues and organs consequent upon our faulty methods of living." This may be true of certain diseases, it is certainly not true of small-pox, malaria, yellow fever and a host of other infections. Written for the purpose of frightening the layman such exaggeration may be good politics, but it creates an unfavourable impression on the minds of scientists. Apart from this general defect of the book, it can be warmly recommended as stating very forcibly the reasons for believing that unsuitable diet causes stasis and is responsible for a vast amount of disability. There is little fear of the medical man being misled by the exaggerations contained in the book and for this reason it is desirable that Mr. Barker's graphic indictment of constipation should be widely read. The general public will probably be thoroughly frightened and perhaps the result will be a wholesome

reform in the dietary of some of the millions who are constipated. Europeans in India are probably greater sinners in the matter of diet than any others: a perusal of this book will be in their interests.

THE ERADICATION OF LEPROSY FROM THE WORLD.—By Ezra Bradford Stelner, M.A. Cuttack: Orissa Mission Press. Pp. 175. Price, Rs. 5.

THE aim of this book as stated by the author is "to discover a solution for the eradication of leprosy from the world." The book might more accurately be described as an account of leprosy from certain points of view, such as history, mode of infection, and means of prevention by treatment and segregation. The greater part of the book is composed of quotations from the recognized authorities on leprosy: it contains a wealth of material which will be very helpful to lecturers and propaganda workers. A generous tribute is paid to the work of Sir Leonard Rogers, Dr. Victor Heiser and Dr. Ernest Muir, whose combined efforts have changed leprosy from an unspeakable horror to a disease which is usually amenable to treatment. One of the most remarkable of the tributes to the recent treatment for leprosy is contained in the story told by the Superintendent of a leper asylum. Some of the patients were singing at an unusual time of the day, and on being asked the reason for their rejoicing they replied that they "had met to praise God because once again we feel prickly heat." The book will be of considerable interest to all students of leprosy as it presents aspects of the disease which are not ordinarily found in textbooks. Those who seek for information on the diagnosis and treatment of the disease will not expect to find much to interest them.

PULMONARY TUBERCULOSIS: ITS ETIOLOGY AND TREATMENT.—By David C. Muthu, M.D., M.R.C.S., L.R.C.P. Second Edition. London: Baillière, Tindall and Cox, 1927. Pp. 503, with 33 original plates. Price, 12s. 6d. net.

THIS somewhat bulky book has reached its second edition. It contains much of the information which may be derived from most textbooks on tuberculosis and is well illustrated with 27 figures consisting of photographs, charts and diagrams. The main object of the book however seems to be to promulgate the theory held by the author that "the presence of the tubercle bacillus is not a decisive factor in the development of tubercular process..... There is no valid proof that the widespread prevalence of the disease is brought about in the majority of cases by its contagious character."

"All the pieces of suggestive evidence we have thus brought from various sources, when put together give us a right to surmise:

(1) That micro-organisms arise for the most part from within from the altered condition of the blood.

(2) That in turn these pathogenic organisms by a more favourable environment, can become saprophytes and harmless, which coincides with a return to health."

We have to confess that the evidence seems imperfect and is not such as would appeal to those who are familiar with laboratory technique and experimental methods.

The author has a somewhat complicated, philosophical style which is difficult to follow. The book abounds in poetry and platitudes and Latin quotations, but much useful information can be gleaned from its pages by careful perusal.

AIDS TO BIOCHEMISTRY.—By E. A. Cooper, D.Sc. (Lond.), F.I.C., A.R.C.S. (Lond.) and S. D. Nicholas, B.A. (Oxon.), A.I.C. London: Baillière, Tindall and Cox, 1927. Pp. viii plus 188, with 11 figures in the text. Price, 4s. 6d. net.

THIS small handbook is an addition to the popular "Student's Aid Series" and will be found useful by students going up for examination. The book deals

chiefly with the fundamental principles of biochemistry, structural and physiological. Theoretical discussions generally have been left out, only the more important portions being included. A previous knowledge of the subject is necessary to make the best use of the book. It also includes practical work for students.

The book can be recommended as a help to students revising the subject.

MODERN CLINICAL SYPHILOLOGY: DIAGNOSIS—TREATMENT—CASE STUDIES.—By John H. Stokes, M.D. London and Philadelphia: W. B. Saunders Co., 1926. Pp. 1144, with 865 illustrations and text figures. Price, 55s. net.

EVERYTHING from the pen of Professor Stokes is worthy of serious attention. This work is essentially a monograph which embodies the author's personal experience of thousands of cases of syphilis of all kinds seen both at Pennsylvania and at the Mayo Clinic. It is a veritable mine of information, and the practitioner in charge of a syphilis clinic will find in it everything he could possibly require. It is impossible in a brief review to give an adequate idea of the contents of so large a work. A leading feature is the inclusion of numerous case extracts, interspersed throughout the text, to illustrate various types of cases and common mistakes in diagnosis.

We may refer to some of the more salient points. His remarks on the diagnosis of the chancre are very important. He draws attention to the fact that the diagnosis of an early case of syphilis has undergone radical alteration in the last fifteen years. He refers to Fournier's large work in which 239 closely printed pages are devoted to a description of the clinical appearances of the chancre, which is now of academic interest only; he states "much of the factor of error now existing in the diagnosis of early syphilis is, I believe, the product of the survival of antiquated morphologic notions of the appearance of the chancre as an aid to diagnosis, and the persistence of the habit of teaching medical students the untrustworthy differential criteria of pre-spirochetal days. If the medical student will learn that there is no way to identify a genital lesion except by the dark field, the local and the blood Wassermann reactions, he will be a much safer servant of the public than with his present equipment of half-truths about induration, erosion, multiplicity, painlessness and so forth." In support of this he gives some excellent illustrations showing typical "chancres" which are however not syphilitic lesions at all. The Wassermann method described is that of Kolmer. A brief description of the precipitation tests for syphilis is given. His opinion on this point is "the basis of reference for their efficiency has, however, been the Wassermann test, and to a properly performed Wassermann test they remain thus far subsidiary, and on the whole less trustworthy." This is in agreement with our own views.

Among the wealth of illustrations we see none of chancres of the female generative organs.

In the treatment of anomalous cases, he agrees with the British view that diagnosis must precede treatment, and that if it be impossible to make a diagnosis at the moment, extremely watchful waiting must be carried out. He condemns treatment on a doubtful diagnosis, and takes the cautious view that if this is ever done, the course of treatment must be as thorough as if a diagnosis of syphilis had been definitely made. This question is however a difficult one, as if treatment be instituted very early, less treatment is required.

In the treatment of neuro-syphilis, while he agrees that there is real, though in experienced hands, slight risk to the eyes in the use of trypanamide, yet he prefers this drug to malarial therapy, which in his opinion is by no means free from danger, and which he regards as a last resort. A good deal of space is allotted to intraspinal treatment. He is prepared cautiously to advise this in certain cases, as, though the margin of safety is small, the final results are in

his view better. He regards intraspinal therapy as definitely a specialist procedure, and not to be undertaken by the general practitioner. He considers that not enough use is made of serology to detect oncoming neuro-syphilis, and that too much use is made of laboratory tests in late neuro-syphilis in determined, though sometimes vain, attempts to remove persistently positive laboratory findings in a clinically non-progressive case.

This is a very fine book which will take its place among standard works on the subject. Our only criticism is that it is rather long. Some portions, particularly some of the earlier sections dealing with the generalities of clinical examination, might be considerably curtailed. The case records given increase the bulk of the book a good deal. Many of these are extremely instructive; others might be omitted. The absence of a bibliography is to be regretted. We think there is much to be said for the plan adopted by some recent authors of a short selected bibliography at the conclusion of each chapter giving reference to a few original papers of outstanding importance.

We have derived much benefit from reading this most excellent book—printed on good paper with splendid illustrations—by an acknowledged authority, and we heartily recommend it to every practitioner wishing to familiarise himself with the modern aspects of syphilis.

THE MODERN TREATMENT OF HÆMORRHOIDS.—

By J. F. Montague, M.D., F.A.C.S. London: J. B. Lippincott and Co., 1926. Pp. x plus 296, with 116 illustrations. Price, 21s. Obtainable from Messrs. Butterworth and Co., Calcutta. Price, Rs. 15-12.

THE author essays to bring before the reader the whole subject of hæmorrhoids, especially with regard to the modern treatment.

The first nine chapters deal with a description of the affection, its pathology and diagnosis. Seven chapters are set aside for the discussion of the various methods of treatment, therapeutic, operative, by injection, by radium, and electrotherapeutic. The last three chapters deal with complications, recurrence, etc., concluding with a bibliography.

A clear account is given of the author's method of treatment and other well-known authorities are referred to. The author favours the operative method for radical cure in suitable cases, but freely discusses the advantages and disadvantages of other procedures, whether prophylactic, palliative or curative. It is interesting to note that the "ligature with excision" method recommended for the radical cure of piles is almost identical with the operation adopted by Harrison Cripps many years ago; there can be no doubt as to the soundness of this procedure. It is wisely admitted that individual operators are justified in following various other methods, to which they have become accustomed. The more modern methods, such as by injection, by radium, or electrotherapeutic, are described and discussed.

Stress is laid on the importance of a simple routine and a full consideration of the feelings of the patient. There is ample evidence that the author's work is based on a large personal experience and the book can be confidently recommended to surgeons as a reliable guide.

The illustrations, diagrammatic and photographic, are clear and well-chosen. A feature which is annoying to some English readers is the American method of spelling. On page 139, the supine position is described as the "prone" position.

F. P. C.

PHYSIOLOGY AND BIOCHEMISTRY IN MODERN MEDICINE.—By J. J. R. Macleod, M.B., LL.D. (Aberd.), D.Sc. (Tor.), F.R.S. Fifth Edition. St. Louis: The C. V. Mosby Co., 1926. Pp. xxxii plus 1054, with 281 illustrations, including 9 coloured plates. Price, \$11.00.

THE fact that a book has reached the fifth edition since its first publication in 1918 leaves little doubt

that it is appreciated. The real utility of this work lies in the fact that it appeals to all ranks of the profession who desire to keep in touch with advances that are essential in the practice of modern scientific medicine, whether of a theoretical or practical nature. The volume is well got up and the various sections are up to date. From the point of view of criticism it is possible that the scope attempted in the book is too ambitious and might be rendered more valuable by judicious curtailment. The book as a whole can be thoroughly recommended, not only to the consultant but more especially to practitioners and students who wish to keep abreast of the study of scientific medicine.

T. C. B.

THE QUEEN CHARLOTTE'S PRACTICE OF OBSTETRICS.—By the members of the staff of the Hospital. London: J. and A. Churchill, 1927. Pp. 692, with 4 coloured plates and 270 text figures. Price, 18s. net.

It is indeed with pleasure that we welcome this volume, the first to appear for a long time, representing the teaching and practice of the London School.

The book is excellently printed and illustrated, and bears the impress of opinions based upon practice, rather than on theory. The toxæmias and disorders associated with pregnancy, are particularly valuable chapters, and Section 7, dealing with pyrexia in the puerperium, is quite the clearest and most practical account of the subject that has been written in any textbook up to date. The premature baby is given a chapter to itself, and the chapter on the unhealthy baby cannot fail to be of use to all practitioners. Obstetric operations are dealt with in a separate section in the end of the book, whilst perhaps one of the most interesting chapters of all is the miscellaneous one which deals with such subjects as anæsthetics, pituitary extract, x-rays, and maternal mortality. The reviewer, who has delved through a host of Scotch, American, and Irish textbooks during the last few years, has no hesitation in stating that this is by far the clearest, and most practical exposition of the subject that he has had the pleasure of reading for a long while and is of the opinion that it is undoubtedly the best textbook for students in this country to buy.

V. B. G-A.

BASAL METABOLISM IN HEALTH AND DISEASE.—By E. F. Du Bois. Second Edition. London: Baillière, Tindall and Cox, 1927. Pp. 431, with 1 plate and 99 figures. Price, 22s. 6d. net.

A GREAT deal of importance is nowadays attached to the subject of basal metabolism. Previously, it was the physiologists, the biochemists and the research workers only who had to deal with the measuring of basal metabolism, and the author is to be congratulated on his attempt to bring this subject out of the realm of pure physiology into that of clinical medicine. The book is written in clear language and will be found useful to practitioners in medicine and surgery, as well as to medical students. The chapter dealing with the metabolism of carbohydrates, protein and fats is an interesting study and will be very helpful in getting a clear idea as to what changes are taking place inside the body during the metabolism of these food principles.

The author has discussed fully the general fundamental principles of the technique of the basal metabolism test and has described some of the principal apparatus used for the purpose, such as the Atwater-Rosa-Benedict respiratory calorimeter, the Benedict cot chamber, the Tissot apparatus, Douglas' bag, Benedict's portable apparatus, etc. He has fully described the advantages, disadvantages and limitations of each kind of apparatus, which we consider to be a most useful section for those who have to do work of this kind.

The author has fully and clearly demonstrated the importance of determination of the basal metabolism

in various diseases such as diabetes, diseases of the thyroid, diseases of the other endocrine glands (adrenals, pituitary, sex glands, etc.) and the chapters dealing with this subject will prove very useful to every medical man. In addition, the basal metabolism in diseases of the blood such as primary and secondary anæmias, leukæmias, in cardiac diseases, in nephritis and in fevers has received careful consideration from the author.

We have no hesitation in recommending the book to the medical public.

DISEASES OF THE SKIN.—By Henry Hazen, A.M., M.D. Third Edition. St. Louis: C. V. Mosby Company, 1927. Pp. 572, with 248 illustrations, 2 in colours. Price, \$10.

THIS is one of the numerous excellent books on skin diseases: there must be an insatiable demand for books on dermatology, and some ingenuity must be needed to discover new features such as would justify the production of a fresh addition to the large family of dermatological publications. In the preface to the first edition the author had already disarmed criticism by announcing his adherence to the policy of excluding the rare diseases. The author has made a valiant effort to exclude the word eczema from the book and has nearly succeeded, but it is doubtful whether this procedure will be popular with the general practitioner. The attempt to give a rational classification of skin diseases cannot be regarded as being quite successful; for example, among the diseases due to emotional or organic nervous disorders are included urticaria, genital pruritus, alopecia areata, dermatitis artefacta, etc. Altogether it would appear to be premature to depart from the orthodox system of classification of the many diseases of unknown ætiology. The book is very well illustrated and will be found a useful addition to the libraries of the numerous medical men who learn best from looking at good pictures.

CATALOGUE OF INDIAN INSECTS, PART XII—TABANIDÆ.—By R. Senior-White. Calcutta: Government of India, Central Publication Branch, 1927. Pp. 70. Price, Re. 1-12 or 3s.

THIS catalogue of the Indian Tabanidæ, chiefly based on the previous work of Miss Ricardo, brings up to date our present knowledge of the distribution and synonymy of these insects. It contains a key to the identification of the several genera, and synoptic tables for the identification of the Indian species of each genus. It gives a good list of synonymy and a bibliography. This publication is of interest to the entomologist as also to veterinary, and possibly medical officers, since it deals with an important group of insect pests of live stock, some of which are transmitters of surra.

M. O. T. I.

OUTLINES OF COMMON SKIN DISEASES, INCLUDING ERUPTIVE FEVERS.—By T. Caspar Gilchrist, M.D. London: Baillière, Tindall and Cox, 1927. Pp. 54, with 60 figures in the text. Price, 7s. net.

THE want of a book on diagnosis of the common skin diseases has long been felt by students and medical practitioners. This study of dermatology in the Johns Hopkins University, U. S. A., by Dr. T. Caspar Gilchrist, M.D., for 20 years has resulted in the publication of a book entitled "Outlines of common skin diseases" which has tried to remove this long-felt want. The author has first of all given a good, brief classification of the common skin diseases. Then he has outlined his methods for diagnosis. Next he has detailed his methods of diagnosis by describing the ætiology, regional distribution, and characters of these skin lesions. He has laid much stress on two points, namely, the characters of the primary lesions and the regions of the body affected, and these two points are really the most useful guides for diagnosis. Finally,

to aid in the diagnosis, he has given a large number of diagrams which are essential and even more useful than written descriptions. He has completed the book by giving a suitable diet list. On the whole, the book is a most useful guide to lecturers and students, although, because in the tropics the incidence of common skin diseases is different, the book may not prove as useful in India as in temperate climates.

G. P.

THE ARTIFICIAL LIGHT TREATMENT OF CHILDREN IN RICKETS, ANÆMIA AND MAL-NUTRITION.—By Katherine M. L. Gamgee, M.R.C.S. (Eng.). London: H. K. Lewis and Co., Ltd., 1927. Pp. xx plus 172, with 16 plates and 33 text illustrations. Price, 10s. 6d. net.

THIS is a thoroughly practical little book, written from the point of view of an Officer of Health for Maternity and Child Welfare.

In his preface Professor Leonard Hill draws attention to the ill-nourished child "whose stomach is overloaded with the wrong food at the wrong time," as well as the influence of "overstrain, lack of sleep and the quiet which so many poor and overcrowded homes lack." "The author," he writes, "has intimate experience of these homes, and this together with her practical experience of the treatment of children with artificial sunlight gives her book a high value."

After a description of the child of our big industrial areas there are chapters on rickets, sunlight—natural and artificial—and the therapeutic action of artificial light in children.

Part II deals with the practical and administrative organisation of a public health light clinic.

Parts III and IV are concerned with clinical, practical, and statistical problems.

While the book contains nothing new, as a synopsis of the author's practical experience, it will be a great help to those contemplating the establishment of public light clinics.

PYEOGRAPHY: ITS HISTORY, TECHNIQUE, USES AND DANGERS.—By Alex. E. Roche, M.A., M.D., M.Ch. (Camb.), F.R.C.S. (Eng.). London: H. K. Lewis and Co., Ltd., 1927. Pp. xlv plus 118, with 16 plates. Price, 8s. net.

THE contents of this volume are based on 58 personally observed pyelographs at St. Peter's Hospital, London. After a brief history of the development of pyelography, there are chapters on technique, reactions, and complications after the operation, contra-indications, a radiographic study of the normal renal pelvis, and common indications for the operation. These are followed by an account of pyelography in the various renal conditions in which this procedure has been found to be of use. At the end of each chapter there is a short summary which will be found very useful for reference. The printing of the text, and reproduction of skiagrams leaves nothing to be desired and is worthy of the high reputation of the publishers. The work needs no further commendation than that given in the introduction by the distinguished urologist, Sir T. Thomson Walker, who writes: "The increasing number of surgeons who can safely carry out this method of examination, and the necessity that all those engaged in general practice should know the possibilities in diagnosis that it offers, make this monograph a welcome addition to surgical literature."

THE INVERT AND HIS SOCIAL ADJUSTMENT: AN ANOMALY.—By Anonymous. London: Baillière, Tindall and Cox, 1927. Pp. xxxii plus 160. Price, 5s. net.

IN his preface to this very remarkable little book, the author states that he hopes it may be of "particular use to those who find themselves at a loss to provide practical advice for patients or penitents of confused sex." The author, admittedly himself an invert, is

obviously a man of culture and deep religious feeling. Within the limitations imposed by his sex, race and religion, he has acquired a penetrating understanding of and sympathy with, sexual inversion. It will seem to some readers of this book that the author has perhaps shown more concern for the mental and physical welfare of male inverts than they either need or desire. Most male and nearly all female inverts, exhibit, in addition to what the author describes as a "definite clan of youthfulness," a singular complacency in their defect. It is on this latter account that they are so difficult to treat, in the medical sense. In his discussion of the causes and treatment of inversion, the author displays much common sense and no little wisdom, although, it must be admitted, he does not appear to appreciate fully the most recent findings of psycho-analysis in regard to homosexuality which lie probably nearer to the truth than do any other. Dr. Robert H. Thouless, lecturer in psychology in the University of Glasgow, has contributed a preface in which he expresses his own views as follows:—"We who are normally sexed must realise that the virtuous love of a homosexual is as clean, as decent, and as beautiful a thing as the virtuous love of one normally sexed. In other respects it is different in its biological uselessness as a means of continuing the race, in its impossibility of a satisfactory outcome, and in the unwisdom of even its most innocent modes of expression." The book deserves fully to realise its author's hope that it should, "through the agency of charitable physicians, clergymen or other advisers, find its way into the hands of many persons to whom it may be a source of comfort and encouragement."

O. B. H.

THE CATECHISM SERIES.—Edinburgh: E. & S. Livingstone. *Anatomy, Bones; Fourth Edition, Part VI. Physics; Third Edition, Part II.* Price, 1s. 6d. each plus postage.

We have dealt previously with several volumes of this excellent series of little handbooks, and the above two volumes recently issued are well up to the general standard of the series. The one on bones is very complete; and in 89 small pages covers the whole subject. Read in conjunction with a skeleton and a disarticulated skull, it should give the medical student a very sound knowledge of what is perhaps the most difficult subject in anatomy.

The complete series of these little books to date is as follows. Each part is sold at 1/6, plus postage.

Anatomy.—Six Parts. (Third and Fourth Editions.)

Bacteriology.—Two Parts. (Third Editions.)

Botany.—Two Parts. (Third Editions.)

Chemistry.—Two Parts. (Third Editions.)

Diseases of the Ear, Nose and Throat.—One Part. (Just Published.)

Diseases of the Eye.—One Part. (Second Edition.)

Diseases of the Skin.—One Part. (Just Published.)

Forensic Medicine.—One Part. (Second Edition.)

Gynaecology.—One Part. (Fourth Reprint.)

Histology.—One Part. (Second Edition.)

Materia Medica.—Three Parts. (Third Editions.)

Revised according to the New B. P. Or, in one volume, cloth, 4s. 6d. net. Post 4d.

Medicine.—Five Parts. (Second and Third Editions.)

Or, in one volume, cloth 7s. 6d. net. Post 6d.

Mental Disease.—One Part. (Just Published.)

Midwifery.—Two Parts. (Third Editions.)

Operative Surgery.—Three Parts. (Fourth Editions.)

Or, in one volume, cloth, 4s. 6d. net. Post 4d.

Pathology.—Five Parts. (Third Editions.) Or, in one volume, cloth, 7s. 6d. net. Post 6d.

Physiology.—Four Parts. (Third and Fourth Editions.)

Physics.—Two Parts. (Second and Third Editions.)

Public Health.—Two Parts. (Third Editions.)

Surgery.—Five Parts. (Fourth Editions.) Or, in one volume, cloth, 7s. 6d. net. Post 6d.

Surgical Anatomy.—Three Parts. (Second Editions.)

Or, in one volume, cloth, 4s. 6d. net. Post 4d.

Toxicology.—One Part. (Second Edition.)

Tuberculosis.—One Part. (Just Published.)

Veneral Diseases.—One Part. (Just Published.)

Zoology.—Three Parts. (Second Editions.) Or, in one volume, cloth, 4s. 6d. net. Post 4d.

New Part—in Preparation: Diseases of Children.

AIDS TO THE DIAGNOSIS AND TREATMENT OF DISEASES OF CHILDREN.—By John McCaw, M.D. (R.U.I.), L.R.C. (Edn.). Sixth Edition. London: Baillière, Tindall and Cox, 1927. Pp. viii plus 330. Price, 4s. 6d. net.

THIS is an excellent little book of 330 pages, filled with information which cannot fail to be of value to the general practitioner. It is thoroughly up to date with regard to infant feeding and rickets, and summarises the published verdicts of well recognised authorities on many special subjects, such as for instance "sleepy sickness," the Schick reaction, pyloric stenosis, acidosis, etc. The printing is excellent and the text has not been boiled down into the far too frequent telegraphic style of writing.

Dr. Allen, the new editor, is to be congratulated on a very distinct improvement over the 5th edition, and we feel sure that his efforts will be thankfully acknowledged by many medical practitioners all over the world.

THE PRESCRIBER'S COMPANION.—By M. P. Dikshit. Revised Edition. Published by the author at Kurwar, District, Sultanpur, 1927. Pp. viii plus 736. Price, Rs. 15-12.

THE book contains over 3,300 prescriptions under different heads of diseases alphabetically arranged, including prescriptions for children. It also contains a list of incompatibles, numerous useful tables, a section on toxicology with descriptions of symptoms, fatal doses, fatal period, treatment, and chemical tests. The book will be quite useful to general practitioners.

CHRONIC RHEUMATIC DISEASES: THEIR DIAGNOSIS AND TREATMENT.—By F. G. Thomson, M.A., M.D., F.R.C.P. and R. G. Gordon, M.D., D.Sc., M.R.C.P. (Edn.). Bombay: Oxford University Press, and London: Constable and Co., 1928. Pp. viii plus 202. Price, 8s. 6d. net.

THE authors have acquired a wide experience of these diseases at Bath and have evolved some order and system from the chaos, which has resulted from confused nomenclature. The term rheumatism has for years been applied to a variety of conditions differing widely in causation and pathology. The authors have set themselves the task of sorting out these conditions, and have given a very readable, and what is more a logical account, based on the pathology of the lesions. It is only in this way that sound treatment can be applied. The book is divided into three parts, clinical, diagnosis, and principles of treatment, and the ground is very thoroughly covered. In addition, treatment is outlined for all the various special manifestations described in the clinical part. This is one of the best books covering chronic rheumatic affections, including neuralgias and neuritis, that it has been our pleasure to have read.

ANATOMICAL, PHYLOGENETICAL AND CLINICAL STUDIES ON THE CENTRAL NERVOUS SYSTEM.—By B. Brouwer. London: Baillière, Tindall and Cox, 1927. Pp. xii plus 67, with 16 illustrations. Price, 11s. 6d. net.

THE HERTER lectures are delivered each year by some eminent foreign worker in physiology or pathology. The lectures have been published for many years in the *Bulletin of the Johns Hopkins University*, but last year they were issued for the first time in book form. Professor B. Brouwer of Amsterdam visited Baltimore last year to deliver the lectures. The professor is a clinician in neurology, but a perusal of this book reveals him as a physiologist, and a clinical pathologist as well.

He delivered three lectures and each of them is on a rather abstruse subject. The first is entitled, "The Projection of the Retina on the Brain." The lecturer first points out how experiences during the war renewed our interest in the cerebral organisation of the optic pathways. He gives full credit to the workers in the subject and mentions that many years ago Newton emphasised that in man the optic fibres only partly cross in the chiasma. He describes the anatomical differences in various animals, and then summarises the theories of the localisation of the retinal fibres proceeding to the brain that have been held by different authorities.

The lecturer describes his experiments and their results. The actual surgical operations on the eyes of animals were performed by Professor Zeeman. The operation performed was intricate and calls forth the admiration of the reviewer. The retina was injured with a cataract needle in a predetermined and definite area. This operation was carried out under general anaesthesia, and with the aid of an ophthalmoscopic lens of 20 dioptries the point of the needle and the fundus were always in view of the operator. The resulting degenerated areas of nerve tissue were examined post-mortem and many interesting results obtained.

The lecturer discusses these results, and undoubtedly adds much to our knowledge of optic localisation in the brain. The second lecture is entitled, "The Pathology of Sensibility" and this difficult subject is presented in a most interesting manner.

The importance of the study of comparative anatomy is emphasised, and many experiments are described. The value of intrathecal injections of lipiodol is explained. Since using this method for localising tumours of the spinal cord the surgeons have never failed to find the tumour at operation.

The third lecture is entitled "The Significance of Phylogenetic Studies for the Neurologist." It is at once apparent that the lecturer has always been very interested in the comparative anatomy of the nervous system. He shows clearly that such a study is of great importance in helping the investigator to understand the many problems with which he may be confronted. The book is well printed and the diagrams are very clear. It is difficult to judge the value of this book to the medical profession in India. To the neurologist and to the ophthalmic surgeon it should prove most interesting, for both of them will find aspects of their work presented in a most interesting and novel way.

H. H.

A TEXTBOOK OF CLINICAL NEUROLOGY.—By Israel S. Wechsler, M.D. London and Philadelphia: W. B. Saunders Company, 1927. Pp. 725. Illustrated. Price, 32s. 6d. net.

In a way clinical neurology may be regarded as the Cinderella of the system diseases in medicine. Recently great advances have been made in many directions, such as in diseases of the heart, the kidneys, the endocrine glands. These have not been accompanied by any corresponding advances in our knowledge of the nervous disorders. Consequently in taking up a new textbook of clinical neurology, such as the one before us, we do not expect to find anything very original in the subject matter. This holds good in the case of the present volume. In one important way, however, the author has departed from custom. Whether this departure is an advantage to the reader we take leave to doubt. The departure from tradition lies in the omission of the usual, and in our opinion essential, introductory chapters on the anatomy and physiology of the nervous system. The author maintains that these subjects can be learned more completely from special textbooks. This no doubt is true, but we believe that for a true and proper appreciation of neurology it is essential to leave this knowledge in its proper setting, and to keep constantly in mind and at hand for ready reference a complete map of the whole nervous system and its connections, particularly the motor and sensory paths. It must be available for instant reference and cannot be divorced from the

subject matter of the text. This can only be accomplished by incorporating it in the book. A knowledge of these requisite details, motor and sensory, is the open door to an intelligent comprehension of nervous diseases and a textbook without them is like a house without a door. The brief anatomical outlines given in some instances by the author by no means take the place of a collective anatomical survey.

The book is divided into five parts. The first part deals with the various methods of examination. The portion on the electrical examination of nerves and muscles is particularly good. The reaction of degeneration is clearly defined—a point of some importance. In sixteen years' teaching experience the reviewer has never met a student capable of giving a complete and correct definition of this reaction. Professor Wechsler's description should make the matter clear to the dullest. There is a mistake in the letterpress below Figs. 7, and 8. Fig. 7 is, of course, the anterior view and Fig. 8, the posterior. A full description of the new method of "chronaxie" for the diagnosis of muscle nerve degeneration is given. "Chronaxie" is the shortest duration during which a current of certain defined strength must flow through a muscle-nerve in order to produce a contraction. The current strength chosen as the unit of measurement is called the "rheobase." Measurement is made by means of electrical condensers. The method is introduced by the French and is likely to be of considerable value. In this part is included a useful section on the technique of lumbar puncture and the examination of the cerebro-spinal fluid. Part I concludes with a description of the psychometric tests, and their importance, apart from any question of mental defect, is stressed.

In Part II diseases of the spinal cord are discussed and a clear and concise account of them given. The section on the muscular atrophies is the least satisfactory portion of this part, and the classification given is not very helpful.

Part III deals with the peripheral nerves, Part IV with the brain, and Part V with the neuroses.

The book as a whole is readable and presents the somewhat dry facts of clinical neurology in an interesting manner. It is a book more likely to be of use to the practitioner than to the student, but can be read with profit by all interested. There is an excellent selection of references at the end of each section. The printing, binding and illustrations are faultless.

J. D. S.

A SHORT ACCOUNT OF THE ANTIQUITY OF HINDU MEDICINE.—By David C. Muthu, M.D., M.R.C.S., L.R.C.P. (Lond.). Second Edition. London: Baillière, Tindall and Cox, 1927. Pp. 52. Price, 2s. 6d. net.

THIS booklet gives a very interesting statement of the reasons for believing that Hindu medicine and Hindu civilization are of extremely ancient origin. The great antiquity of the Indo-Aryan civilization is well known, what is not clearly known is the region from which these worthies of old came. Perhaps it does not matter much whether they originated from the Punjab or from some more western land, at any rate it is clear that their manners, customs and beliefs approximated more to those of Europe than is the case among their descendants in India to-day.

Dr. Muthu deals with the various periods of life in India:—

- (1) From 6,000 B.C. to 4,000 B.C.
- (2) From 4,000 B.C. to 2,500 B.C. (the Rig Veda and Ayar Veda).
- (3) 2,500 to 600 B.C.—the Epic Period when the Indo-Aryans reached the height of their civilization. Charaka and Susruta flourished in this period.
- (4) 600 B.C. to 600 A.D.—The Buddhist period during which a decline set in, anatomy, dissection, and surgery being discouraged.
- (5) 600 A.D. to 1600 A.D.—the Arabian period during which Hindu medicine still further declined,

though it is claimed by some that much of the Arabian and European medicine was borrowed from Hindu sources.

Dr. Muthu's work should stimulate the present generation of Indian medical men to strive to restore the glorious past, by imitating the example of the great thinkers of the past. Would that Charaka and Susruta could be born again in India! They would certainly be in the van of modern research and would have little patience with those whose lack of initiative dishonours their distinguished predecessors. Let us do homage to the great physicians of old, by trying to make full use of all existing knowledge and experience: what we need is something of their spirit and enterprise, rather than a slavish return to their actual methods.

J. W. D. M.

MUSCULAR CONTRACTION AND THE REFLEX CONTROL OF MOVEMENT.—By J. F. Fulton, B.Sc., M.A., Ph.D. (Oxon.). London: Baillière, Tindall and Cox, 1926. Pp. xv plus 644, with 204 figures in the text. Price, 45s. net.

THIS imposing volume is a monograph concerned primarily with the activity of skeletal muscle, its mode of contraction, and the nature of its reflex control. The first part deals with the phenomena associated with contraction of the individual muscle fibre, and the second with the way in which the individual fibre responses are summated by the central nervous system into the postures of living organisms. Recent advances in the physiology of muscle and central nervous processes are fully described, and a detailed description is given of the torsion-wire myograph of Professor Sherrington, and its use in conjunction with the string galvanometer. A brief historical sketch of the physiology of muscle has been given in the introduction. This in itself is interesting reading, inasmuch as it deals with the life work of such great men as Aristotle, Galen, Galvani (to mention a few), by whom so little has been accomplished in comparison with what remains to be known.

One of the features of the book is the comprehensive bibliography, the references in which have been personally verified by the author. It is essentially a book for the physiologist, and as such should form part of the library of every one interested in the teaching of this subject.

J. A. S.

VENEREAL DISEASE: ITS PREVENTION, SYMPTOMS AND TREATMENT.—By Hugh Wansoy Bayly, M.C. Third Edition. London: Faber and Gwyer, Ltd. Available from Butterworth and Co. (India), Ltd., Calcutta, 1927. Pp. 242, with 3 coloured plates and 74 illustrations in the text. Price, 10s. 6d. net, or Rs. 7-14.

THE second edition of this book was reviewed at length in our issue for October, 1924, and the appearance of a third edition is evidence of the demand for the book and of the desire of the author to keep abreast of modern developments. The general character of the work was sufficiently noticed in our former issue, so that it will suffice to remind the reader that it is essentially clinical and practical and is intended for the general practitioner. The student will not find the pathological aspect of the subject dealt with in sufficient detail for his needs, but for practitioners the work will be found a concise practical guide. The chapter on prevention will be useful, as practitioners often have to advise on this point, but it is somewhat overburdened with historical matter which is out of place in such a short manual. The space thus occupied would be better devoted to a more detailed account of the clinical features of secondary syphilis. The question of the diagnosis of active syphilis on the evidence of a positive Wassermann reaction alone, in the absence of history or clinical signs, is a difficult one and all will not agree with the author's views on this point, but until the technique of the Wassermann reaction and its interpretation have been absolutely standardised the question must remain open. The reviewer, working with the

same laboratory under standard conditions for some years finds that he can accept a positive Wassermann reaction alone as evidence of active syphilis, and has not yet seen a case in which patient treatment has failed to modify or reverse that reaction, thus justifying his contention. Considerable perseverance both on the part of patients and doctor is often necessary, and one cannot accept results from any and every laboratory, as the meaning of slight and doubtful reactions is different in patients with a proved history of syphilis and in those tested under suspicion. The essential point is that the laboratory should be in such close touch with the clinician that doubtful points of this nature can be cleared up by personal reference; if this condition is fulfilled most of the difficulties in the interpretation of the Wassermann reaction will disappear. The author does not see any advantage in the use of intramuscular arsenical injections because they are often slightly painful, but it is in these cases of persisting positive reactions that intramuscular injections have proved their great superiority over intravenous injections. The long period of observation advised for cases of syphilis—10 years—is rarely practicable, but the author's view on the marriage question are eminently reasonable.

The treatment of general paralysis of the insane by malarial therapy, by protein shock and by tryparsamide is considered in sufficient detail and there are sections on the use of diathermy in both the male and female. The exaggerated claims which were made for this treatment when it was introduced are assessed at their true value and its real field of usefulness is indicated. There is a mistake in the description of the diathermy apparatus, a rotary converter is necessary if the supply current is a direct one and not for alternating current as stated. The illustrations are well reproduced, particularly the three coloured plates the sources of which are duly acknowledged.

W. L. H.

PRACTICAL GASTROSCOPY.—By J. Rachet, M.D. Authorised translation by F. F. Imlaniloff, D.Sc., B.A., M.R.C.S. London: Baillière, Tindall and Cox, 1927. Pp. xii plus 146, with 10 plates and 48 figures in the text. Price, 15s. net.

THIS little book is essentially one for the expert, and although the translator states "it is not yet possible to claim gastroscopy as a method of routine examination, yet it has become a daily possibility," we are inclined to disagree. In the first place a very careful selection of cases has to be made; and of the selected cases in only about one-third can the lesion be recognised, and then only by one who has had considerable experience of the method. The practical value of such a method of diagnosis must be very small. This book itself, however, is interesting reading. The style is lucid, and it is well illustrated. It can be recommended to all those who are interested in that branch of optics which has for its object the illumination of the cavities of the human body. Indeed the author can be congratulated on having made an intensely interesting contribution to medical science.

A MANUAL OF SURGERY (ROSE AND CARLESS) FOR STUDENTS AND PRACTITIONERS.—By Albert Carless, C.B.E., M.B., M.S., F.R.C.S. and C. P. G. Wakeley, F.R.C.S. (Eng.), F.R.S. (Edn.). Twelfth Edition. London: Baillière, Tindall and Cox, 1927. Pp. xii plus 1544. Illustrated. Price, 30s. net.

THIS well known surgery, familiar to every student for the last thirty years requires no further notice than the fact that, after three years, a new edition is necessary.

There is a slight increase in the illustrations with however a slight reduction in the total number of pages. The chapter on anaesthesia has been revised and is well worth perusal. The preface contains a long eulogy of Lord Lister and his work and is well worth reading. A feature of this new edition is the attention paid to emphasizing the initial symptoms of disease rather than

the terminal phenomena. This marks a distinct and necessary advance in surgical textbooks and for this reason alone the student and practitioner should obtain the new edition and discard the old one.

There are some beautifully coloured plates.

H. B. S.

A SYNOPSIS OF SURGERY.—By Ernest W. Hey Groves, M.S., M.D., B.Sc. (Lond.), F.R.C.S. (Eng.). Eighth Edition. Bristol: John Wright and Sons, Ltd., 1927. Pp. 674, illustrated. Price, 17s. 6d. net.

THE book is of great help to the student for the purpose of a quick revision of a bigger textbook before an examination. It will also be found useful by the general practitioner in quickly refreshing his memory, as the book though brief is both readable and comprehensive. It is the most excellent and complete synopsis of surgery that we have so far seen.

THE INJECTION TREATMENT OF VARICOSE VEINS.—By A. H. Douthwalte, M.D., M.R.C.P. (Lond.). London: H. K. Lewis and Co., Ltd., 1927. Pp. viii plus 39. Price, 3s. net.

THE little pamphlet is both interesting and instructive. The description of the technique of the injection method of treatment of varicose veins is very lucid. This method should be given a thorough trial by all surgeons, as the operative method of treatment is still far from satisfactory. The book may strongly be recommended to all practising medical men.

THE PRINCIPLES OF ANTE-NATAL AND POST-NATAL CHILD HYGIENE.—By W. M. Fieldman, M.D., B.S., M.R.C.P. (Lond.), F.R.S. (Edin.). London: John Bale Sons, and Danielsson, Ltd., 1927. Pp. xxiv plus 743, with 161 illustrations and 14 plates. Price, 25s. net.

THIS is the most complete textbook on the subject of child hygiene that we have yet seen. No aspect of the subject is left untouched. The author has a wide knowledge of child hygiene and communicates his knowledge in an easy but elegant, literary style. Despite the detail, it is a very readable book. The illustrations are numerous and add greatly to the interest of the book. The history and development of child hygiene is dealt with in the opening chapters; to ante-natal, inter-natal and child mortality there are devoted four chapters. A clear description of heredity and environment in relation to child hygiene is given. Antenatal hygiene is discussed physiologically and pathologically. It would serve little purpose to detail farther the headings of chapters, but we can assure our readers that they will find complete up to date information on every point of child hygiene given in an interesting but at the same time authoritative manner. Every one interested in the subject practically or theoretically should be in possession of this book. The quotation on the title page is apt:—

"Are you not risking the greatest of your possessions? For children are your riches, and upon their training for well or ill depends the whole order of their fathers' house."

THE EVOLUTION OF PREVENTIVE MEDICINE.—By Sir Arthur Newsholme, K.C.B., M.D., F.R.C.P. London: Baillière, Tindall and Cox, 1927. Pp. xv plus 226, with 6 plates. Price, 11s. 6d. net.

THE value of the study of history and historical appreciation in political and national matters has long been recognised; it is but lately however that the history of medicine has received its proper place in the medical curriculum. Many leading schools have now chairs in the History of Medicine, and students have an opportunity of appreciating the steps by which medicine has become a rational science, and of the lines along which it is now proceeding and likely to advance. Sir Arthur Newsholme is well known as a medical author, and in addressing himself to the task of writing a short history

of the evolution of preventive medicine he has placed the profession under an obligation. A history of preventive medicine is much needed, but Sir Arthur found that the task was so formidable that he had to be content with a shorter sketch than he originally had intended writing. But the shorter book will probably reach a wider circle of readers than the larger volume.

The author points out that the proper place of preventive medicine is alongside curative medicine. Only when we understand fully the causation and the remedy for disease can we approach the task of prevention with assurance. The principles of preventive medicine are closely bound up with the history of medical science and the story is an entrancing one to look back on. It is one of a constant fight of originality versus authority. As has happened in most religions, so in medical science sacerdotalism and priestcraft in authority and dogma have always stifled advance and have often done the original founder much harm. To demonology and to wrathful offended deities for long were attributed all the diseases and epidemic outbursts of the plagues that have afflicted mankind. Hippocrates was the first to break away from the fetters of supernaturalism; and Aristotle and Plato were among the first exponents of the application of reasoned intelligence to disease. Galen, while forming the culminating point of Greek medicine and apostle of experimentation, was at the same time the leader of extreme unfounded dogmatism, and his presumed authority for centuries opposed all progress.

The early Christian priesthood, through a misreading of Christ's teaching, underrated this mortal life, and for about 1,200 years priestcraft, charlatanry, impostures and saintly charms masqueraded as medicine.

Roger Bacon (1214) was a light born out of his time. Paracelsus (1500), himself a bit of a charlatan, broke the ice of authority, while Galileo and Copernicus achieved the emancipation of reason which has gone on since.

In England Harvey and Francis Bacon lit the lamp of experimental philosophy which will now never be dimmed. Bacon's great service was in helping to release mankind from the obsession of untested doctrines. The further history of science, philosophy, and medicine, curative and preventive, is a fascinating story which Sir Arthur Newsholme delights in the telling. England can be proud of her part in this story; Harvey, Sydenham, Baker, Farr, Pringle, Mead, Boyle, Jenner, Murchison, Howard, Simon, Chadwick, Southwood Smith, Lister, Manson, and Ross are names fit company for those of Hippocrates, Galen, Plato, Malphighi, Da Vinci, Pasteur, Koch, Semmelweis, Laennec, Metchnikoff, and Ehrlich.

The story naturally resolves itself into a history of the discovery of the causation and means of spread of the main diseases and pestilences, cholera, small-pox, plague, and malaria, and of the means of combating these. The road through ignorance, superstition, prejudice, conceit and arrogance and indifference is a rough one and not always has it been the path to glory for the traveller. A realisation of the possibilities of human life along with hard work and applied knowledge, conviction and personal practice are the weapons of emancipation to the individual and to the masses. The process goes on, now faster, now slower, but always; and the perusal of this volume will instruct and encourage all those who have to preach and practice the ways and means of health.

A. D. S.

HEALTH SUPERVISION AND MEDICAL INSPECTION OF SCHOOLS.—By Thomas D. Wood, A.M., M.D. and Hugh Grant Rowell, A.B., M.D. London and Philadelphia: W. B. Saunders Co., Ltd., 1927. Illustrated. Pp. 637. Price, 35s. net.

THIS is a very complete and detailed account of the activities of the methods of health supervision and medical inspection of school children as carried out in the United States of America. The method of arrangement, however, makes it a difficult book to read. All the

information given is catalogued and classified by numbers, a system which kills any literary style, and makes reading the book a somewhat tiresome task. Each chapter is replete with specimen forms, records, scoring cards, tests, tables, reports, instructions, regulations, etc.; and while these are undoubtedly illustrative, they convert the book into a reference manual, and are apt to detract attention from the text, much of which is of great interest. The "scoring card" system is much in vogue in America now, and is used to assess mental intelligence, health, dairies, school construction, desks, etc. These are no doubt valuable, but too much cataloguing is apt to rob any study of its interest, and we sympathise with Keats for whom the rainbow was ruined by being put into the "dull catalogue of common things."

There is a wealth of information in the book, but not much of real practical application to Indian conditions.

A. D. S.

ELEMENTARY SANITARY ENGINEERING IN INDIA.

—By G. Bransby Williams. Third Edition. Revised and Enlarged. Calcutta: Thacker, Spink and Co., 1928. Pp. viii plus 133. Price, Rs. 6.

THE Inspector of Nuisances, or the Sanitary Inspector as he is now more euphemistically called, has played a very important part in the development of environmental sanitary science. He was and still is, the immediate instrument of the local authority both for detecting and remedying defects in the sanitary conditions of the village, the township and the municipality. To the Sanitary Inspector an elementary knowledge of sanitary engineering is essential. In England such instruction is given at the Royal Sanitary Institute. In Bombay courses of instruction are given under the auspices of the Institute. In Bengal the Public Health Department arranges for courses of teaching for sanitary inspectors, who at the end of their training in hygiene and sanitary engineering undergo examinations. Mr. Bransby Williams' manual is meant for these classes, and provides the theoretical and descriptive parts to supplement the practical and outdoor instruction. The chapters are well arranged and cover a large amount of ground, map reading, drawing, surveying, building construction, drainage, sewage and waterworks are all dealt with in concise and clear language.

There are about 30 plates of diagrams which illustrate the text matter very well. Health officers, Directors of Public Health, and students wishing for a clear description of the elements of sanitary engineering will find the book valuable. The matter is treated in an essentially practical manner and the author draws on his large experience to give authoritative descriptions and opinions.

The printing and the plates are excellent.

A. D. S.

MOSQUITO SURVEYS: A HANDBOOK FOR ANTIMALARIAL AND ANTI-MOSQUITO FIELD WORKERS.—By Malcolm E. MacGregor. London: Baillière, Tindall and Cox, 1927. Pp. 282, with 3 maps and 59 other illustrations. Price, 15s. net.

THIS work can be thoroughly recommended to the medical man without special entomological training, or even as a refresher to those whose taking of the D.T.M. is a long-past event, and to engineers and planters who wish to acquire the foundations of anti-mosquito entomology, but except in Part III it contains nothing that the professional malariologist would not consider the basic part of his entomological training.

Unless the author is assured of a heavy sale in the Mascarene Islands, we think the book would be more likely to "go" in the tropics in general if Mauritius was relegated more to the background. In any case this impression would be less marked if a general account of these islands did not open the book, or if this had been transferred to Part II, which is apparently written specially for Mauritian workers.

Part III, field and laboratory hints, we have nothing but praise for. There is no worker, however, long his

experience, who will not profit by a study of pages 184 onwards; hence the book must be added to the library of every medical entomologist.

It is easy to criticize minor points, but we would point out that the Nematocera are not all small, some of the Tipulids are among the largest of living diptera. Personally we have never heard of the four apical joints of the tarsus being described as "metatarsals," and it is better in any case to drop the use of this term even for the basal joint of the tarsus, as it has no homology with the vertebrate joints of the same name. In Fig. 11 the part that the author has, correctly, referred to as the post-scutellum is here called the metanotum, and the fact that the latter name is a survival from an older nomenclature is not pointed out.

For a simple account of the male genitalia such as is required for systematic purposes, we prefer Christophers' and Barraud's to that of Edwards, (*Ind. Jl. Med. Res.*, X, 827-835). On page 75 the homology of the mouth brushes of the larva is, as usual, left unexplained, whilst the statement on page 79 that palmate hairs are found on segments 3-5 of most Anopheline larvæ is misleading, as those who work with the book as their first introduction to the subject will seldom have any difficulty in discovering these on other segments also.

The account of the Mauritian mosquito fauna, which forms Part II of the book, will be invaluable to all workers in the Mascarene Islands, but the writer is fortunate in having to deal with a local fauna of such paucity that a complete account of its various species can be included in so small a book. Within the tropics, there is hardly anywhere else where this could have been done.

R. S.-W.

A SHORT ILLUSTRATED GUIDE TO THE ANOPHELINES OF TROPICAL AND SOUTH AFRICA.—By Alwen M. Evans, M.Sc. London: Messrs. Hodder and Stoughton, Ltd., 1927. Pp. 64 with 10 text figures and 12 plates. Price, 9s. 6d. net.

ANOTHER work identifying the Liverpool School with the development of the New Dominion. Keys to African Anophelines have previously appeared from the pens of Edwards (1912), and Carter (1919), while Christophers (1924) has included them in his more general catalogue of the Anophelini of the world.

The author's key however brings the subject right up to date, after consultation with all the latest work on the subject, of which a good bibliography is appended. An early Victorian dichotomous "key" was merely a weariness to the flesh and despair to a student, but in these enlightened days such works are heavily illustrated, altogether a different matter; and one day indeed some Bolshevik will publish a key with no text at all and only draw groups of visual pegs on which to hang up the required names. In this case the author's drawings are a delight, and have been produced in a most enviable manner, as indeed has the whole work.

Beside the key there is a short description of other salient factors in the life of each species, including notes illustrated by plates on their breeding places, all of which information should greatly help the local officers concerned in their efforts to lay the malarial ghost.

There is no doubt but that local keys of the Anophelines are the first requirement in any malarious locality, and the present work amply meets this want as far as the adults of the species are concerned.

C. S.

STANDARD METHODS OF THE DIVISION OF LABORATORIES AND RESEARCH OF THE NEW YORK STATE DEPARTMENT OF HEALTH.—By A. B. Wadsworth, M.D. London: Baillière, Tindall and Cox, 1927. Pp. xx plus 704, with 12 plates and 70 figures in the text. Price, 34s. net.

THE Director of the Division of Laboratories and Research of the New York State Department of Health

had been in the habit of issuing to his various laboratories and departments detailed instructions with regard to laboratory methods and procedure. These instructions were not an unalterable dogma, but were continually being revised when the advance of scientific knowledge necessitated a change, or when better methods of achieving the same end were devised. These directions, usually drawn up by the heads of the several departments concerned and constantly improved throughout more than a decade by contributions from the staff, have been collected and published in the form of the volume under review.

The book is essentially a practical one but its scope is very wide. After giving a short review of general laboratory methods, including the housing and methods of using laboratory animals, detailed instructions with regard to the cleaning and sterilization of glass-ware and the preparation of media are given. This is followed by a section on the methods used in diagnostic laboratories; here directions are given for the opening, labelling and filing of specimens. Detailed instructions are given for the routine examination of various pathological specimens and methods for identification and isolation of various pathogenic organisms. There is a section on the methods employed for the examination of water, milk, sewage and so forth. One of the largest sections in the book is devoted to the details of preparation of vaccines and antisera. Finally there are two sections on the methods employed in the executive offices and in the research, publications and library departments.

There is much in this volume which is not applicable to Indian conditions, but officers in charge of any bacteriological, vaccine or serum manufacturing, or Public Health laboratories will certainly find many valuable suggestions, both for general procedure and for technique, in these pages.

The reviewer found it hard to follow the plan of arrangement of the section on methods employed in the diagnostic laboratories. In one or two instances certain well-known methods which are distinctly better than those described appear to have been overlooked; for example in describing the withdrawing of blood from the ear of a rabbit no mention is made of the well-known device of dipping the ear into melted paraffin so that the walls of the vein do not collapse and stop the flow of blood. The bibliography is meagre and the titles of the papers are omitted; this is, we think, a mistake. The book on the whole is, however, an excellent one, the illustrations are useful, and the text clear and readable.

L. E. N.

LOCAL IMMUNIZATION: SPECIFIC DRESSINGS.—
By A. Besredka. Translated by H. Plotz, M.D.
London: Baillière, Tindall and Cox, 1927. Pp. xl
plus 187. Price, 16s. net.

THIS is the English—or perhaps one should say American—translation of Besredka's well-known book. It is an extremely readable book. It is not crowded with monotonous details of experiments, but a few experiments are quoted to demonstrate each point which the author wishes to make. To explain his theory he has taken four type bacteria, or groups of bacteria, two of which infect the skin and two the intestinal mucosa.

The book should certainly be read by anyone who wishes to understand thoroughly Besredka's theory—a theory which is not likely to be accepted as a whole, but which will certainly leave its mark on the science of bacteriology. The theory is dependent on the observation of the specific susceptibility of certain groups of cells to certain organisms. The anthrax bacillus when introduced into the subcutaneous tissues does not produce anthrax, but when it is rubbed into the scarified skin or injected into the layers of the skin anthrax follows. Again, when a living culture of dysentery bacilli is injected into the blood stream the animal does not get a septicæmia, but the bacteria rapidly disappear from the blood and on the death of the animal can only be found in the mucous membrane and in the lumen of the intestine and gall-bladder. In the same way immunity is specific to a certain degree. Immunity to intraperitoneal

inoculation may be produced in an animal which will leave it susceptible to a skin infection by the same organism, and *vice versa* skin immunity can be produced without the corresponding intraperitoneal immunity.

The last chapter in the book is devoted to theoretical considerations, or, to use one of the author's quotations from Pasteur, to "the illusions of the experimenter, which serve as a guide, and which gradually fade as we travel along the road." The author claims to have presented in his theory of local immunity the truth as it appears to-day. The reviewer finds himself almost entirely convinced by the author's arguments and even the most sceptical will admit that it is a theory which cannot lightly be brushed aside. The author himself does not claim that his theory will stand for ever; theories disappear, but the facts remain.

L. E. N.

TEXTBOOK OF BACTERIOLOGY.—By William W. Ford, M.D. London and Philadelphia: W. B. Saunders Co., Ltd., 1927. Pp. 1089. Illustrated. Price, 37s. 6d. net.

THIS is still another textbook of bacteriology, and as it has to enter into competition with many excellent rivals there ought to be some good excuse for its appearance. The special feature of this book is that the selection of micro-organisms for description is based chiefly on the personal observation of the author. It is impossible to write a complete "system of bacteriology" and the author has wisely refrained from making the attempt; he may fairly claim to have given a sufficient account of all the bacteria which are concerned in causing human disease. Special attention has been paid to the spirochaetes and filtrable viruses. Protozoa are not dealt with. Methods of laboratory technique are given in some detail but a knowledge of the manipulation of the microscope is assumed to exist.

Many methods of staining, culture, etc., are described and to each is appended a reference to the original account of the method as given by its originator. The illustrations are good, all are drawn approximately to the same scale and every effort has been made to show the forms which are truly typical.

The plague bacillus is described as having been discovered almost simultaneously by Kitasato and Yersin: in an advanced textbook like this it would be only fair to give in a few words the original descriptions by the two men who first discovered the bacilli; these leave little room for doubt that the bacillus described by Kitasato was not the real plague bacillus at all.

The accounts of the bacteria which are selected for description are very full, accurate and clear. The Wassermann reaction is very briefly referred to; the Widal reaction is hardly mentioned; vaccine preparation is dealt with in two pages in a general way, and evidently such "side lines" are not regarded as coming within the scope of the book.

The organism of undulant fever is called *Bacterium melitense*, and perhaps the author might have dealt a little more fully with the question of its relationship with the *Bacterium abortus*. In the case of both these organisms the author without explanation or apology describes them as the *Bacillus melitense* and *Bacillus abortus* in the detailed account.

The classification of the spirochaetes can hardly be regarded as settled: the author has adopted the rather confusing method of giving separate accounts of all the spirochetes without attempting to discuss their relationships; perhaps he has been wise in doing so, though the student will be left with an impression of vagueness and confusion similar to that which is produced by reading some modern descriptions of the fungi which occur in skin diseases.

Noguchi's views regarding *Leptospira icteroides* are given without any reference being made to the doubts which exist in the minds of many experts as to its causal relationship with yellow fever. Still another spelling is adopted for the sandfly which carries sandfly fever, viz., *Phlebotomus papatassii*.

This book forms a most valuable guide to the advanced worker; it will take its place in every bacteriological laboratory, but it is in no sense a students' textbook.

BACTERIAL VACCINES AND THEIR POSITION IN THERAPEUTICS.—By Leonard S. Dudgeon, C.M.G., C.B.E., F.R.C.S. Bombay: Oxford University Press, and London: Constable and Co., 1927. Pp. 87. Price, 7s. 6d. net.

THIS forms an excellent summary of existing knowledge of the use of vaccines in the prevention and treatment of disease. Its most valuable feature is that there is no exaggeration in the claims made for the various systems of vaccine treatment. It is impossible to lay down dogmatic rules in connection with such controversial points as the value of prophylactic vaccination against influenza and colds, but the reader will find Dudgeon's work a sane and reliable guide.

H. W. A.

SEGREGATION AND AUTOGAMY IN BACTERIA.—By F. H. Stewart, M.A., D.Sc., M.D. London: Adlard & Son, Ltd., 1927. Pp. 104. Price, 7s. 6d. net.

THIS book, which is very highly technical, describes the author's view on the segregation and autogamy in bacteria. It deals largely with the mutation changes in the *Bacillus coli communis* and the *Bacillus dysenteriae* (Flexner), and the typhoid bacillus. The author however neglects the work of d'Herelle and others showing how these mutation changes may be brought about as the result of bacteriophage action. These mutation forms are then resistant to the action of the bacteriophage.

The author is difficult to follow in his summary and in the deductions he has drawn as the result of these experiments. There is a good deal of indiscriminate reasoning by analogy from the protozoa to bacteria, which is always a dangerous method to adopt in substantiating a theory.

H. W. A.

INTRODUCTION TO THE STUDY OF THE ANATOMY AND PHYSIOLOGY OF THE EYE.—By Dr. Max Coque, B.Sc. London: J. and R. Fleming, Ltd., 1927. Pp. 458.

THIS is an unusual book, published for the instruction of prescribing opticians, and very ambitious in its scope, as it attempts in a short scope to deal with the general principles of physiology and pathology in the human body, and especially the physiology of the eye, as well as the detailed anatomy of the eye and orbit, and the usual methods of examination of the eye, both healthy and pathological, all in the short space of 445 pages. Needless to say it is very compressed and uneven, giving curious details in some points not usually in books, especially in connection with comparative anatomy and physiology, and in others it is very brief, and only to be followed by one having already a fair general knowledge of biology. The best part of this publication is the excellent series of stereoscopic photos provided with a simple form of stereoscope, which give a really good idea of the general bony anatomy of the orbit, and the macroscopic anatomy of the dissected eye. This is really good and useful, whereas one fears the text of the book, while possibly useful for those for whom it has been written, will be found of little use to medical men who have access to the many good textbooks on the eye.

RECENT ADVANCES IN OPHTHALMOLOGY.—By W. Steward Duke Elder, D.Sc., Ph.D., M.D., Ch.B., F.R.C.S. London: J. and A. Churchill, 1927. Pp. 343, with 4 coloured plates and 73 text figures. Price, 12s. 6d. net.

THIS book, the last issue of this good series, is well up to the standards of the previous volumes, and is a really valuable resumé, well put together and balanced. It starts with a discussion on the nature of light and

its influence on the eye; accommodation, according to modern views, and the causes of haloes; and deals mainly with the more scientific aspects of these problems in a very good clear way. It then deals briefly with the recent work in embryology and the recent methods of diagnosis, slit-lamp, red-free light and anterior gonioscopy. This part is short but good and very well illustrated with coloured plates. The physiology of the eye is then dealt with, the intra-ocular circulation, intra-ocular pressure, and the nature of the fluids of the eye, especially from the bio-chemical point of view, and this forms a preparation to the consideration of the diseases of the eye, high blood pressure and its results, retinal hæmorrhages, and glaucoma. This last is treated in considerable detail and the recent theory associating this disease in part at least with changes in the hydrogen-ion content of the blood is well put forward.

Cataract is described in the light of slit-lamp researches, its pathology discussed and the effects of light on the lens nutrition pointed out, and recent views on sympathetic ophthalmitis described, though the recent note of Jackson in the *American Journal of Ophthalmology* as to the comparative rarity in the diagnosis of this condition since Wassermann reaction blood tests became common is not mentioned. Photo-therapy, its use and abuse, and the newer methods of local anaesthesia are briefly described, and the book concludes with a very good and fairly detailed description of the recent neurology of the eye.

The stimulating and interesting character of the book as a supplement to the usual large textbooks will be obvious from this short resumé, and one can strongly recommend all those interested in eye work to get it and read it carefully, though in places they will probably find it fairly stiff reading.

OPHTHALMIC YEAR BOOK, VOL. XXIII. CONTAINING BIBLIOGRAPHIES, DIGESTS AND INDEXES OF THE LITERATURE OF OPHTHALMOLOGY FOR THE YEAR, 1926.—Edited by William H. Crisp. Chicago: Ophthalmic Publishing Co., 1927. Pp. 338.

THIS book continues to serve as a valuable reference record of the ophthalmic literature of the past year, and the present volume is well up to the standard of its predecessors. It is unfortunately, however, the last of its series, as difficulties in its production and want of support have made it impossible for the publishers to continue to produce it in this form, as a Supplement to the *American Journal of Ophthalmology*. It is hoped, however, that the series may be carried on in another form, and a hint as to the possibility of this appears in the *American Journal of Ophthalmology*, and one can only hope that these efforts will be successful.

THE BLOOD VESSELS OF THE HUMAN SKIN AND THEIR RESPONSES.—By Thomas Lewis, M.D., F.R.S. London: Shaw & Sons, 1927. Pp. 322. Illustrated. Price, 37s. 6d. net.

WE must congratulate the author of this excellent work on the physiology of the blood vessels of the skin. The book has been well got up and the illustrations have been very finely reproduced by the publishers. The work opens up a new line of thought about the nature of the reaction of the finest and larger vessels of the skin to different stimuli. Every worker in dermatology should possess this work, which gives a clear description of how to investigate the mechanism of arteriole and capillary action. We consider that Krog's work on the pressor substances in the posterior lobe of the pituitary gland in maintaining tone as regards permeability should also have been considered by the author. Sir Thomas Lewis has particularly studied the action of various kinds of stimuli on the different vessels of the skin, or clearly demonstrates that the finest vessels are not under a nervous control. He considers that when the skin is stroked by a hard object, the red line is due to the mechanical stimulus, whilst the flare and

wheel are due to the liberation of a theoretical H. substance, which acts like histamine on the vessels of the skin.

According to this theory, the tissues of different individuals would vary in the amount of damage caused to them by these mechanical stimuli. Thus when the damage was greatest we would get a marked red flare followed by a large wheal. We know that in persons who are susceptible to toxic bodies from foods, etc., this susceptibility is largely due to loss of control of these fine vessels. The tone is maintained by various means, the amount of pressor substances circulating in the blood from the posterior lobe of the pituitary gland, the calcium content of the blood, and the amount of adrenalin circulating in these vessels. When one or other of these factors are deficient in the blood, the poisons can act on the vessels and give rise to urticaria, etc. The production of bullæ is due to increased permeability of the capillary loops under the basement membrane, so that serum flows into the intercellular channels, whilst in urticaria the permeability affects the finer vessels in the region of the subcapillary plexus, giving rise to cedema in the corium. When both types of vessels are involved, bullous urticaria is seen in the skin. Therefore in epidermolysis bullosa the mechanical injury causes dilatation of the capillary tufts, and the formation of bullæ, whilst in dermatographia, the same type of stimulus causes the flare and wheal.

H. W. A.

DISEASES OF THE SKIN.—By Robert W. Mackenna, M.A., M.D., B.Ch. Second Edition. London: Baillière, Tindall and Cox, 1927. Pp. 450, with 36 coloured plates and 143 illustrations in the text. Price, 25s.

THE second edition of this book has been revised thoroughly, and considerably enlarged. There are 36 excellent coloured plates illustrating various skin diseases. We can strongly recommend this book to those medical practitioners who require a medium sized book on dermatology. The teaching is given very clearly and lucidly. There are many views that are expressed in this book that we do not agree with, but they are however the accepted and orthodox teaching in dermatology. As the author states, the science of dermatology is passing through a phase of extraordinary rapid growth and development, and the reader will find in this work a well balanced and up to date presentation of the subject.

H. W. A.

THE COMMON DISEASES OF THE SKIN.—By R. Cranston Low, M.D., F.R.C.P. Edinburgh: Oliver & Boyd, 1927. Pp. 223, with 68 illustrations. Price, 14s. net.

THIS small book on skin diseases gives very concisely the orthodox teaching in dermatology that is given at present to students, and can be strongly recommended as a primer for those students in England studying dermatology. The book is of little value to workers in the tropics, as the common diseases like leprosy, etc., that are met with so commonly in our dermatological clinics in India are dealt with very briefly. This, however, does not detract from the value of the book, which is one of the best of these small primers on dermatology. The main lesions that are seen on the skin in the common diseases are fully and concisely described in it. The book is well got up with 68 illustrations, 8 of which are coloured.

H. W. A.

RONTGEN RAYS IN DERMATOLOGY.—By L. Arzt, M.D., and H. Fuhs, M.D. London: Baillière, Tindall and Cox, 1927. Pp. xiv plus 202, with 5 coloured plates and 57 figures in the text. Price, 18s. net.

THE authors of this book on the value of "Rontgen rays in Dermatology," unfortunately for English readers, describe only the different kinds of German apparatus;

instead of giving the type of apparatus employed in a particular case. The section on X-ray dermatitis and the biological effects of X-rays is excellent and is illustrated by coloured plates. The chapters deal with the affections of the hair that are amenable to X-rays such as, favus and ringworm; the specific granulomata, this chapter mainly comprising the effect of these rays on tuberculides and on diseases of the nails. The keratoses are then described separately, but little or no stress has been placed on the value of medicinal treatment in these cases.

There is an appendix at the end which gives the dosage employed in the various skin diseases that these authors have given to their cases. The formulæ at first sight look complicated, but one can soon read them when the nomenclature has been understood. We can thoroughly recommend this book to those workers, who are using Rontgen rays in the treatment of skin diseases.

H. W. A.

X-RAY AND RADIUM IN THE TREATMENT OF DISEASES OF THE SKIN.—By George M. Mackee, M.D. Second Edition, thoroughly Revised. London: H. Kimpton, 1927. Pp. xii plus 788, with 354 engravings and 31 charts. Price, 45s. net.

THE first edition of this work appeared in 1922 and it was very favourably received by the medical profession. This—the second edition—contains so many additions and alterations that it may be considered almost a new book—174 pages, 104 illustrations, and 300 literary references have been added. Apparatus, and technique are fully dealt with. No fewer than seven chapters are devoted to the various methods of measuring X-ray dosage. The author, in the preface to this edition, points out that X-rays and radium are dangerous modalities in unskilled hands, and every physician who employs them should have a thorough training in their use, in addition to a general medical training, and moreover should possess modern equipment. We are in full agreement with him in this respect. We also agree with Pusey's statement, repeated by the author, that "It is the consensus of opinion that X-rays constitute the most important single therapeutic agent in the armamentarium of pure dermatology. Radium, whilst being of great value to the dermatologist is of far less importance than are the Rontgen rays." Finally, we can only say that the fine reception given to the first edition is certain to be repeated in the present instance, as the book is one which should be on the bookshelf of every skin specialist, radiologist, and medical practitioner who is interested in the treatment of skin diseases.

ACTINOTHERAPY FOR GENERAL PRACTITIONERS.—By H. G. Falkner, L.R.C.S.I., L.R.C.P.I., L.M. (Rot. Dub.), O.B.E. London: Baillière, Tindall and Cox, 1927. Pp. x plus 152, with 36 figures in the text. Price, 7s. 6d. net.

THIS little volume, written principally for the general practitioner, is an intensely practical production. The author realised that the ordinary practitioner has little time for study: but while omitting all unnecessary detail, important chapters such as those on protection of glasses, elements and electrodes, and lamps, have been compiled with great care.

The chapters on the treatment of diseases are written in a racy manner, and the claims made for ultra-violet ray treatments are well balanced, e.g., in dealing with sciatica, the author says, results depend on the cause—"If due to pressure upon the nerve, no good can be expected; but if due to cold, good results nearly always follow." Such discrimination in writers on this subject is refreshing.

At the end of the book there is a short summary of diseases with their appropriate treatment which should prove more than useful to general practitioners.

Finally, we are of opinion that no medical practitioner, whether he intends to dabble in this branch of medical science or not, should be without this practical little volume.

ULTRA-VIOLET RADIATION AND ACTINOTHERAPY.—By E. H. Russell, M.D., B.S., and W. Kerr Russell, M.D., B.S. (Dub.). Second Edition. Edinburgh: E. & S. Livingstone, 1927. Pp. viii plus 439, with 247 illustrations. Price, 15s. or Rs. 11-4. Obtainable from Messrs. Butterworth and Co. (India), Ltd., Calcutta.

THIS is the second edition of one of the best known works on actinotherapy. The first edition was well received by the medical profession and the present edition which has been enlarged and brought up-to-date should be equally well received.

The arrangement of the subject matter is excellent, the style lucid and free from verbosity. It is profusely illustrated. The chapters on technique, with the description of the various forms of arcs, lamps, and accessories are particularly good.

The chapters on treatment of various diseases are characterised by an absence of extravagant claims, such as one finds in most books on actinotherapy.

We can thoroughly recommend this little book to all who are interested in actinotherapy—to the expert for its wealth of technical detail; to the beginner for its guidance in selection of apparatus, the types of disease which react favourably, and the results which are likely to be obtained.

J. A. S.

A SYNOPSIS OF PHYSIOLOGY.—By A. Randle Short, M.D., B.S., F.R.C.S., and C. I. Ham, M.D., B.Ch., M.R.C.S., L.R.C.P. Bristol: John Wright and Sons, Ltd., 1927. Pp. 258. Illustrated. Price, 10s. 6d. net.

THIS volume adds another number to the series of synopses on medical subjects issued by the same publishers. The object of the book is stated as being to give a fairly full summary of modern physiology in a small compass. That the authors have succeeded in their main object cannot be doubted. It is unquestionably the most comprehensive synopsis of human physiology which it has been our good fortune to meet. We have made a critical search for something to find fault with, and with the exception of one or two misprints, have discovered nothing to criticize. The treatment of most of the subjects is necessarily dogmatic and restricted, but no important points are left unmentioned and every paragraph is up to date.

We cannot help thinking that this book is a dangerous weapon to place in the hands of the average student, however, more especially in India. Physiology is a subject which should not be learned by rote. It is a subject that, forming the foundations of medicine and surgery, should be studied widely from different angles, and this book, which professedly contains all the information on the subject necessary to pass even advanced examinations, will tend to foster the habit already ingrained in the Indian student of committing pages of writing to memory.

Nevertheless this book will come as a boon to the advanced student studying special branches of this subject, to the practitioner, physician, or surgeon who wishes to keep abreast of the times, and as an aide-mémoire to the lecturer on this fascinating subject.

For the general plan of the book, the arrangement of the subject matter, and the general up-to-dateness and of the information, we have nothing but the highest praise.

J. A. S.

PIERSOL'S NORMAL HISTOLOGY, WITH SPECIAL REFERENCE TO THE STRUCTURE OF THE HUMAN BODY.—Edited and Rewritten by W. H. F. Addison, B.A., M.D. London: J. B. Lippincott Co., 1927. Pp. 477, with 43 coloured plates and 432 text illustrations. Available from Messrs. Butterworth and Co. (India), Ltd., Calcutta. Price, Rs. 18-12 or 25s.

THIS is the thirteenth edition of Piersol's well-known book on normal histology. This edition has had the advantage of being thoroughly revised and partly rewritten by Professor W. H. F. Addison.

The arrangement of the book is that which is usually followed in books on this subject; first the cell, as an entity, its structure, its vital phenomena, its methods of division, etc., are described; then the elementary tissues are dealt with in a general way; but the bulk of the book consists of a detailed description of the various organs and tissues of the body arranged according to the systems, i.e., blood-vascular system, lymphatic system, etc., to which they belong.

The part of the book relating to protoplasm, cell structure and cell division has been entirely re-written, and considerable additions, including new illustrations and figures, have been made to the sections on the bone-marrow and on blood development. The endocrine glands have been grouped together in conformity with present usage.

Reference is made to the newer methods of study of the living cell, such as microdissection, tissue culture and supravital staining, and descriptions of these are given in the appendix.

A list of selected references is given at the end of the book to pieces of original work which are suitable for the student to read. The author suggests that as part of the routine class work each student should read one or more of these papers and report on them. This seems to be an excellent suggestion, as not only does it teach the student his histology, but it may have the effect of impressing him with the fact that our present knowledge of histology is dependent on the original investigation of the past, and instilling in him a desire to undertake original investigation himself. It is somewhat unfortunate that many of the references are to journals which are not frequently seen in this country.

The format of the book is excellent; the quality of the paper is good; the print is clear; and the text is profusely illustrated, colour being introduced wherever advantage was to be gained by its use.

L. E. N.

A MANUAL OF CHEMISTRY.—By W. Simon, Ph.D., M.D., and Daniel Base, Ph.D. Thirteenth Edition. London: Baillière, Tindall and Cox, 1927. Pp. xvi plus 695, with 6 coloured plates and 55 figures in the text. Price, 25s. net.

THE book is primarily meant for students of medicine and pharmacy. It deals with both inorganic and organic chemistry. The opening section on the fundamental concepts of matter and energy gives a general idea of some of the common scientific terms usually described in physics. In the section on inorganic chemistry, the summary of the analytical characters of the elements and the coloured plates given at the end of the various groups, which form a special feature of this book, are very useful additions for helping students. A special section on analytical chemistry, with practical hints and tables, adds to utility of the book. The author has touched upon practically the whole field of organic chemistry, laying special emphasis on the compounds used in medicine, although one notices a less thorough treatment of this section as compared to the excellent treatment of the inorganic section.

On the whole, the book contains in one neat volume a collection of almost all the useful information required by a student either for medicine or for pharmacy, and it should prove a very good book of reference for them even in their future career.

S. G.

A MANUAL OF PHARMACOLOGY AND ITS APPLICATIONS TO THERAPEUTICS AND TOXICOLOGY.—By Torald Sollman. Third Edition. London and Philadelphia: W. B. Saunders Company, 1927. Pp. 1184. Price, 36s. net.

THE author in the preface says that the dominant object of this manual is to furnish the medical student and the practitioner with an outline of the current conceptions of the actions of drugs, especially from the point of view of their practical importance in medicine. No other book on this subject in the English language succeeds better in this object than the

book under review. Pharmacology is a rapidly growing branch of medicine and much work is being done and many new drugs are being constantly introduced. The third edition of this valuable book is, therefore, very welcome. This present volume has been entirely reset and much new matter has been included and the bibliography has been considerably enlarged. The arrangement of the book is such that it can be used both as a textbook by junior students and as a book of reference by advanced students and practitioners. This book should be in the possession of all those who wish to practice rational medicine.

R. N. C.

MATERIA MEDICA, PHARMACY, PHARMACOLOGY AND THERAPEUTICS.—By Sir William Hale-White, K.B.E., M.D. (Lond.), M.D. (Dub.), LL.D. (Edin.). Nineteenth Edition. London: J. A. Churchill, 1927. Pp. viii plus 712. Price, 10s. 6d. net.

THE nineteenth edition of this popular handbook on materia medica has been revised and the subject matter has been brought up-to-date. The description of many new drugs which have been recently introduced into therapeutics is included in the text. The book forms a very useful and handy volume for students and practitioners alike.

R. N. C.

MATERIA MEDICA FOR NURSES.—By A. Mulr Crawford, M.D., F.R.S.P.S.G. London: H. K. Lewis and Co., Ltd., 1927. Pp. viii plus 86. Price, 3s. 6d. net.

THIS small book has been written with the object of presenting a short summary of the elements of materia medica to the members of the nursing profession. The drugs commonly used, their preparations and dosage, and short notes on their pharmacological action and toxic effects have been concisely given. The general arrangement of the book is good and the classification of drugs adopted is simple and readily understandable. We have no doubt that the book will be useful to the nursing profession.

MUTER'S SHORT MANUAL OF ANALYTICAL CHEMISTRY.—Edited by J. Thomas, B.Sc. (Lond.). Eleventh Edition. London: Baillière, Tindall and Cox, 1927. Pp. xiv plus 238, with 86 figures in the text. Price, 8s. 6d. net.

THIS is a concise but thorough manual for students of analytical chemistry. It deals with practically all the subjects, both inorganic and organic, which are required for medical and pharmaceutical students. Both the qualitative and quantitative sides have been well developed, and make it a very useful and an extremely handy volume, not only for students but also for all the other workers engaged in analytical work.

S. G.

STUDIES IN PSYCHOLOGY.—By William Elder, M.D., F.R.C.P.E., F.R.S.E. London: William Heineman Medical Books, Ltd., 1927. Pp. xv plus 212. Price, 8s. 6d. net.

THIS book expresses another attempt to approach psychology in terms of neurology. The procedure is by no means new, and in this particular instance is fuller than usual of the fallacies which are inevitable to such a method of approach. The author deals with such subjects as memory, emotion, consciousness, sleep, dreams, and what he terms, "allied mental phenomena." Under this heading he includes among other matters hypnotism and somnambulism. A considerable portion of the book is devoted to what is presumably intended to be a refutation of psychoanalytical psychology. The author trots out most of the old, and now somewhat threadbare, objections to the teaching of Freud in such a manner as to make it fairly obvious that he has not taken sufficient pains to understand the fundamentals of Freud's psychology. For instance, the author conceives Freud's conception of the "censor" to be something in the nature of an alter-ego. He writes: "If

the censor is an entity apart from the ego, it necessarily follows that it practically means a return to the old belief in demoniacal possession." Freud's own description of the censor is to the effect that it was a function of consciousness. Freud compares consciousness with a sense organ in that it is concerned with the perception and differentiation of psychical qualities. Its action differs from that of a sense organ in so far that it allows the perception not only of externally produced stimuli, but also of internal psychic processes. Then on p. 199 we read: "Dream interpretation associated with psycho-analysis becomes, then a 'placebo.'" The way in which the author labours to convey to his reader the impression that the whole of Freud's teaching is a mere farrago of nonsense would be only amusing were it not for the fact that Dr. Elder is a Fellow of the Royal Society and of the Royal College of Physicians of Edinburgh. From a member of such learned societies, work of this description cannot ever be amusing. On the other hand, it can be pathetic, which, in this instance, it most assuredly is.

O. B. H.

MENTAL HANDICAPS IN GOLF.—By Theo B. Hyslop, M.D., F.R.S.E. London: Baillière, Tindall and Cox, 1927. Pp. xv plus 112. Price, 3s. 6d. net.

THIS is a very readable little volume, although somewhat long-winded. In fact it is a pity that the author has not taken some of his own advice to heart, and not wasted so much time in addressing the ball. Most of what he says in 100 pages might be condensed into 25, and then the book would be scarcely worth while. The reviewer is informed by a scratch golfer that the proper mental stance is largely a question of practice. The author does not stress this sufficiently. There are recipes for improving one's mental stance which the author entirely ignores. He merely makes the diagnosis but says nothing about treatment. For instance, one of John Ball's tips is never to worry where your opponent's shots go, and one of the best ways to ensure this particular mental stance is deliberately to turn your back on your opponent when he is playing. No doubt this little volume will be widely read, but whether the results will be that the reader's "mental armour may be wrought in metal without alloy" as the author hopes, is another question.

J. A. S.

OPERATIVE DENTISTRY.—By J. D. Hamilton Jamieson, H.D.D., L.D.S. (Edin.). Edinburgh: E. & S. Livingstone, 1927. Pp. 216. Price, 7s. 6d. net. Obtainable from Messrs. Butterworth and Co. (India), Ltd., Calcutta. Price, Rs. 5-10.

THIS is volume IX of the *Outlines of Dental Science Series*, published by E. & S. Livingstone, 16-17, Teviot Place, Edinburgh, pp. 215, with 27 illustrations. 1927. Price 7 shillings.

THIS book aims primarily at putting before the dental examiners of the United Kingdom, the salient points in operative dentistry. There are thirteen chapters devoted to operative dentistry, in all 196 pages. It is evident that the subject matter has been dealt with all too succinctly; in fact the descriptions given of some of the operative procedures are rather brief and would not be very well understood by beginners. A very obvious chapter, namely, one of the anatomy of the teeth has been omitted, to the great detriment of the usefulness of the book. We fail to see how chapter XIV on impression-taking, choice of teeth and crowns comes under the heading of operative dentistry.

The book may be used as a reference book for dental practitioners and students, but it is not meant to take the place of the standard textbooks on the subject. Taking only one example, in chapter VI on hyper-sensitive dentin, no mention is made of one of the most excellent ways of relieving hyper-sensitive dentin, namely by the use of the *gazotherme*. Even if the invention and apparatus be French, science is international and the world would think very poorly of

a dentist who does not know or has not read about a most important instrument for the alleviation of pain, while preparing cavities. Omissions of this nature are many, and are probably due to the fact that the book has been made intentionally short and compact.

The printing and get-up of the book are excellent and are in keeping with the reputation of its well-known publishers.

R. A.

AIDS TO GYNÆCOLOGY.—By R. E. Tottenham, B.A., M.D., D.P.H. (Dub.), F.R.C.P.I. Seventh Edition. London: Baillière, Tindall and Cox, 1927. Pp. viii plus 132, with 25 figures in the text. Price, 3s. net.

This is an excellent little "cream" students' book, with all the important points mentioned, and it should prove useful to those for whom it is intended, provided that they have attended the bedside and theatre clinical lectures. The only merit of such publications is that they are *multum in parvo* compendiums of information, but unintelligible unless the student has seen for himself the conditions and operations so summarily outlined clinically, and can therefore visualise them.

There is a misnomer on p. 41, where for "Wertheim" "Watkins" should be read instead.

Annual Reports.

ANNUAL ADMINISTRATION REPORT OF THE ASANSOL MINES BOARD OF HEALTH FOR THE YEAR, 1926-27. BY J. W. TOMB, CHIEF SANITARY OFFICER, ASANSOL MINES BOARD OF HEALTH.

As most of our readers must now be aware, the Asansol Mines Board of Health is an *ad hoc* sanitary authority charged by law with the prevention and suppression of infectious disease in the coal mining area of Asansol, and with the improvement of general sanitary conditions throughout the area. To these ends it has special powers granted by law, special funds, and a special sanitary staff. Dr. J. N. Tomb is the Chief Medical Officer of the Board. Dr. Tomb's organisation is well known, a trained sanitary inspector working in a "circle" which he can easily visit and control, in close touch with villages and collieries on one hand, and by bicycle and telephone and train with headquarters, is the mainstay of the system. Information regarding infectious disease is quickly obtained, and speedy action immediately possible. The income of the board is obtained from a special cess on the output of coal and from royalty receivers. The report does not state the area of the settlement. The population is about 400,000 and the income is roughly Rs. 1,30,000 and the expenditure Rs. 1,20,000.

The birth-rate for the year was 26.16, and the death-rate 18.48 per mille (not we presume per cent. as the report states). There is thus a very considerable excess of births over deaths, which has been a noticeable feature since 1921. There were 815 cases of cholera with 462 deaths (1.4 per 1,000), most of which occurred in the villages. The spread of the disease was prevented by the various routine measures of the Board's staff. There is no mention however of anticholera inoculation. The research work carried on by Dr. Tomb and Dr. Maitra on the non-agglutinating vibrio found during the cholera season in the population of endemic areas and in unreserved tanks is of very great interest and importance. Small-pox threatened to assume serious proportions but wholesale vaccination and revaccination succeeded in keeping the disease within limits.

Respiratory diseases and "fevers" caused most of the mortality, though malaria was much below the usual. The infantile mortality ratio was 138, a figure which compares very favourably with any place in India.

A feature of the Board's work is the provision of trained midwives and attendance on the women of the settlement during their confinements, while the regular inspection of school children is carried out by a special officer.

Twenty-eight new wells were constructed during the year.

The report is short but to the point, and illustrates the sanitary progress that can be surely made by a well conceived and well directed active organisation directed against infectious disease.

The Board of Health and Dr. Tomb and his staff are again to be congratulated on an excellent year of work and progress.

A. D. S.

PASTEUR INSTITUTE OF SOUTHERN INDIA, COONOR. ANNUAL REPORT FOR THE YEAR 1926-27. BY LIEUT.-COL. T. H. GLOSTER, M.B., D.P.H., I.M.S., DIRECTOR. MADRAS, SUPERINTENDENT, GOVERNMENT PRINTING.

THE Pasteur Institute at Coonoor again showed a decline in the number of patients treated—415 in this year as against 572 in the previous year—as the result of the policy of widespread distribution of antirabic vaccine to district and headquarter hospitals in the Province. No less than 4,373 persons, however, were treated with vaccine manufactured at the Institute, as against a corresponding figure of 4,044 for the previous year: and these figures show a steady and normal increase. As in former years, the total hydrophobia and failure rates are slightly higher for patients treated with vaccine issued to outside centres than for patients treated at Coonoor; the figures are respectively for total hydrophobia rates 0.66 and 0.83, per cent., and for failure rates 0.57 and 0.43 respectively, but the disparity in the numbers concerned in the two groups is sufficient to throw doubt on the reliability of these results as a test of the value of treatment under the two different sets of conditions. (If anything, the conditions present should militate against the Coonoor figures, for—with vaccine generally available throughout the Province—it is the more severely bitten or late cases that will especially tend to go to Coonoor itself for treatment.) Returns from the different districts are on the whole satisfactory, but Bangalore and Hyderabad are noteworthy for failure to follow up treated patients and to ascertain their after-history.

As mentioned in previous reports, an analysis of the general figures with regard to the prevalence of rabies in the Madras Presidency goes to show that not more than one-sixth of the persons bitten by certainly rabid animals now receive treatment, and the future scope for antirabic work in India is almost unlimited. During the year the outside issue of antirabic vaccine was extended to mission hospitals in the Province. Expenditure on general propaganda work was also sanctioned by the General Committee during the year.

The statistical tables with which the report is illustrated chiefly concern only those patients treated at Coonoor, as it has proved difficult or impossible to obtain exact statistical information with regard to those treated elsewhere. Earliness of arrival is very marked in these tables, and only 35 out of the 415 patients treated arrived later than 20 days after being bitten. The distribution of cases throughout the year is singularly uniform, and there seems to be but little evidence of any rabies season in India. Jackal bite is a very unimportant element in the Coonoor figures—only 838 out of 29,957 persons bitten and treated during nineteen years having been bitten by these animals. Human bites in this table give the unexpectedly high figure of 157 cases, and 63 cases are put down to bites by equines.

The financial section of the report shows how loyally the Institute is supported by local bodies in the Madras Presidency. The total expenditure during the year

was Rs. 81,750: of this sum a very large sum—Rs. 41,305—was realised by the sale of the vaccine to outside bodies. The commercial firms in Madras subscribed Rs. 1,030; the Madras Presidency District Boards Rs. 5,301; and the Madras Presidency Municipalities Rs. 3,802. This shows how dependent the Institute is on local support.

The Coonoor Pasteur Institute at the present moment differs from certain other antirabic institutes in India in its policy of widespread issue of antirabic vaccine throughout the Madras Presidency. This issue of vaccine—it is hardly necessary to add—is most carefully controlled and supervised, and the vaccine is only issued to authorised bodies, such as district and head-quarter hospitals. Nevertheless this issue of vaccine provides an important source of income to the Institute, and is a new departure, perhaps of a somewhat experimental nature. It is difficult to judge of results, since it is so difficult to follow up patients treated in out-station headquarters. The policy, however, is a bold one, and—so far at least—justified in its results.

Correspondence.

NURSING ARRANGEMENTS IN UP-COUNTRY HOSPITALS AND INFIRMARY WARDS.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—The question of adequate nursing arrangements in up-country hospitals, and also in the chronic wards of the more important institutions in large centres, is one which seems to have hardly received sufficient attention. In many cases the general attitude has been to press for a regular nursing service on European lines, and in the meantime to be content with the ordinary untrained ward attendant—ward-boy or ayah—who is usually little better than a *hamal*. It seems clear that under ordinary conditions the average up-country civil hospital will never be able to afford highly trained nurses on any reasonable scale, and it is therefore worth while to consider whether some more economical substitute cannot be devised. A scheme for improving the status and efficiency of ward attendants has been under the consideration of the Bombay Government for some time past, and although, owing to financial stringency, funds have not yet been provided, I hope it may shortly come into operation. Some of your readers may possibly care to know the rough details, and I append them, in case anyone may care to give the proposals a trial elsewhere. The main factor which should make a policy of this kind practicable is the spread of primary education, which is now making large numbers of literate persons available at comparatively low rates of pay. The idea is by offering a small advance on the salaries of the present ward attendants—who are in my experience mostly entirely illiterate—to obtain men and women who can read and write in their vernaculars, and also of a somewhat superior social status to those at present employed. Immediately on entering the hospital, these people start an elementary course of training, with the aid of a simple vernacular manual which would have to be specially prepared, and suitable models and diagrams, many of which are already obtainable from the Red Cross and St. John's Ambulance Associations, a skeleton, and necessary apparatus which would already be available in the hospital. The course would include elementary practical anatomy and physiology, hygiene, and in fact most of the subjects which are taught to regular nurses, but on much simpler lines, and would be carried out under the supervision of the medical staff, and the matron or other trained nurse if available, and it would conclude with a viva voce examination on very practical lines. On passing this examination the attendants would be entitled to a small increase in pay.

Further, in order to encourage the recruitment of the right type of people, the housing question would have to be reconsidered in most of the hospitals with which I am acquainted. Instead of the miserable one-room quarter which is all that many hospitals at present boast, something on the lines of a married sepoy's quarter should be provided, with at least two fair-sized rooms, in addition to a verandah in front and a small yard with wood-shed and washing enclosure behind. With a more intelligent, respectable and literate personnel of this description, trained even on these elementary lines, and properly housed, I feel sure that the work of many of our up-country hospitals would be immensely improved, and I consider that the same principle could be applied, with economy and quite satisfactory results, to the chronic wards of infirmaries and even the larger city hospitals.

A necessary adjunct would of course be a fully trained matron, with one or more staff nurses, to exercise a suitable supervision of the inferior nursing staff.—Yours, etc.,

A. HOOTON, C.I.E.,
MAJOR-GENERAL, I.M.S.

KASAULI,
3rd March, 1928.

FIRST-AID IN RIOTS.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—As riots are unfortunately not infrequent in India nowadays, it seems to me that Government should lay down rules and regulations for the guidance of such independent medical practitioners who happen to be on the spot when a riot occurs, or who live in the close vicinity. It appears to me that the best course for the medical practitioner would be to remain in his house until the police appeared and were able to keep some sort of order. The question of payment of fees for services rendered would next have to be considered.—Yours, etc.,

D. BHARADWAJA, L.R.C.P., L.R.C.S. (Edin.),
L.R.F.P. & S. (Glas.).

GANGOHI, SAHARANPUR,
18th October, 1927.

HYPERTONIC SALINE IN SNAKE-BITE.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—In your issue for October 1924, there appeared a report on a case of snake-bite due to *Echis carinatus* treated with hypertonic saline solution intravenously, by Dr. Chuhar Singh. To my mind this article affords subject for meditation, inasmuch as the case was in all probability cured by the repeated intravenous saline transfusions. The constant bleeding, together with the constant replenishment by saline solution, must have acted by washing the toxin out of the tissues, as it were. The bleeding stopped as soon as the venom was sufficiently diluted. Calcium was therefore contraindicated, contrary to your suggestion in the footnote. The idea strikes me that it stands to reason to try to treat both colubrine and viperine snake-bite cases by a constant slow saline transfusion or repeated transfusions according to indication, while encouraging free bleeding from the site of the wound, together with stimulants to keep up the respiration and the heart. As the aim should be to dilute the toxin sufficiently and to aid its elimination, cathartics, diuretics and diaphoretics should also be of benefit if judiciously employed. Calcium in viperine poisoning will therefore only do harm, while sodium citrate in colubrine poisoning may be beneficial.

I make no mention of antivenene, as it is not generally available in the *mofussil* market, where the majority of snake-bite cases takes place. The private country-practitioner can seldom procure it at the right moment; and without it he is at a loss to find sufficient antidotes to earn the satisfaction of having done all that could be done for his patient. I am of opinion

that there are immense possibilities for the use of free saline transfusion, either by itself or even as an adjunct to antivenene treatment.

As regards the use of potassium permanganate, it can be argued that lavage with a solution sufficiently weak not to provoke sloughing should be more active than the mere packing of the wound with crystals, as a liquid would more thoroughly and more quickly get at the poison in the interstices of tissue substance.

Incisions should only be deep at the site of and just about the bite, while scarification of the whole area distal to the ligatures is also of benefit by letting out much affected blood.—Yours, etc.,

R. K. BHATTACHARYYA, M.B.

NABADWIP.

10th February, 1928.

THE PRICE OF NOVARSNOBILLON.

To the Editor, THE INDIAN MEDICAL GAZETTE.

DEAR SIR.—As we have been advised by the India Office to make known in India our new reduced prices of Novarsnobillon, we are giving below the prices to the medical profession which are now governing in that country.

Novarsnobillon.	Rs.	As.	P.
0.15 gramme	..	0	15 0
0.30	1	4 0
0.45	1	6 3
0.60	1	10 8
0.75	2	0 0
0.90	2	5 9

We are also appending the new prices of Stovarsol which will come into force in India on 1st March, 1928.

Stovarsol.

	Rs.
Bottles of 28 X 4 grain tablets	.. 3
Bottles of 14 X 4 grain tablets	.. 2

We shall be obliged therefore if you will kindly give adequate space to the notice of these alterations in your next issue.

We are, dear Sir.

Yours faithfully.

for MAY AND BAKER LIMITED.

BATTERSEA, LONDON, S. W. 11.

24th January, 1928.

A CASE FOR DIAGNOSIS.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR.—On the 27th September, 1927, I was called to attend a patient at 4-30 p. m. He was a hill boy about 19 years of age. I found him in the following condition.

He was lying on his back with both legs extended; the arms were flexed and placed crosswise on the chest and were shaking. The condition of his hands was very peculiar, they were in the so-called 'obstetric position.' Both his arms and legs were very stiff, and I could neither flex his legs nor extend his hands, although I exerted all my strength. No lock-jaw was present and he could swallow fluids. He was partly unconscious and could not speak distinctly. The temperature was 100°F. I could detect no other abnormality.

At first sight I thought the case to be one of tetanus, but the absence of lock-jaw and of any history of injury was against this. Being unable to diagnose the case I gave his parents the following prescription;

R Potass. bromidi gr. x
Chloral hydratis gr. x.
Aquam ad oz. i.

M. ft. Mist. Four such doses. To be given every two hours until he falls asleep.

Also calcium lactate in 7½ grain doses three times a day.

The next morning the parents reported to me that the boy had fallen asleep after the third dose of the mixture, and I found him much improved. The stiffness of the arms and legs had somewhat diminished. The dose of bromide and chloral was now reduced, and the mixture given three times in the day. On the third day the mixture was stopped. The calcium lactate however was continued for another 8 or 9 days, by which time the patient was completely cured.

I shall be much obliged if any of your readers can throw some light on the case.—Yours, etc.,

A. K. GHOSE, L.M.P.

AMBARI TEA ESTATE,

Note.—Surely a case of tetany? EDITOR, I. M. G.

SUGGESTED USE OF UREA-STIBAMINE IN SEPTIC CASES.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR.—In June 1927 I started the urea-stibamine test for kala-azar in this hospital and was struck by the fact that a positive test consisted in the precipitation of globulin in the blood serum tested.

I discussed this reaction with my Assistant Surgeon, Dr. Sen, and suggested that the reaction might mean that the curative effect of urea-stibamine in kala-azar was partly due to a protein reaction.

Dr. Sen on his own initiative commenced giving urea-stibamine, 0.05 grm. intravenously, to septic cases running a prolonged temperature, in July 1927.

The result was so striking in the first case that we made it a routine to give urea-stibamine to all septic cases not reacting to ordinary treatment.

The first case treated had been running a temperature outside hospital for two months, and was admitted with a bunch of caseating secondarily infected glands in the left axilla. The glands were removed but the temperature persisted in spite of polyvalent serum and intravenous injection of iodine. The blood was negative to the formalin test, but slightly positive to the urea-stibamine test. Two doses of 0.05 grm. of urea-stibamine at two days' interval brought the temperature to normal. Dr. Sen is publishing his results. It is of interest to note that in all septic cases the globulin content of the blood is increased.

I am writing this note, as Sir Leonard Rogers in the *Lancet* for January 14th, 1928, points out that tartar emetic controls prolonged febrile reactions in cases of leprosy, which are being treated with potassium iodide. Does potassium iodide increase the blood globulin and is blood globulin increased in leprosy?—Yours, etc.,

A. H. NAPIER,
LIEUT.-COL., I.M.S.,
Civil Surgeon.

MONGHYR.

Service Notes.

THE I.M.S. DINNER CUP.

THROUGH the kindness of Col. Granger, I.M.S., one of the Secretaries to the I.M.S. Dinner in London, and of Col. Fleming, I.M.S., we are able to publish the engraving below of a silver cup which has been made for the annual I.M.S. dinner in London by Messrs. Carrington and Co., 130, Regent Street, London, who will store the cup, sending it as required to the Trocadero Restaurant for the dinner.

The cup is a copy of a Jacobean steeple cup, but instead of an ebony base has a silver pedestal on which are engraved the names of all the officers who have

presided at the annual dinner since its initiation, as also the names of all Secretaries. Those of our readers who

have attended the dinner will be interested in this new departure.

APPOINTMENTS AND TRANSFERS.

Colonel C. Hudson, C.B., C.I.E., D.S.O., F.R.C.S., I.M.S., to be Honorary Surgeon to The King, Indian Military Forces *vice* Colonel A. N. Fleming, D.S.O., M.B., I.M.S. (retired), 9th September, 1927.

Colonel R. W. Knox, D.S.O., M.B., F.R.C.S., I.M.S., to be Honorary Surgeon to The King, Indian Military Forces, *vice* Colonel E. L. Perry, D.S.O., I.M.S. (retired), 24th June, 1927.

The Viceroy and Governor-General has been pleased to make the following appointments on His Excellency's personal staff, with effect from the 28th February, 1928:—

To be Honorary Surgeon.

Lieutenant-Colonel C. A. Sprawson, C.I.E., M.D., F.R.C.P., I.M.S., *vice* Lieutenant-Colonel F. F. Elwes, C.I.E., M.D., I.M.S. (retired).

Lieutenant-Colonel F. E. Wilson, I.M.S., Residency Surgeon and Chief Medical Officer in Baluchistan, is appointed to officiate as Civil Surgeon, Quetta, in addition to his own duties, with effect from the 1st January, 1928, and until further orders.

Lieutenant-Colonel F. E. Wilson, I.M.S., an Agency Surgeon is appointed to be Residency Surgeon and Chief Medical Officer in Baluchistan, with effect from the 1st January, 1928.

Consequent on the grant of leave to Colonel J. D. Graham, C.I.E., I.M.S., Lieutenant-Colonel F. P. Mackie, O.B.E., M.D., F.R.C.P., F.R.C.S., D.P.H., I.M.S., Director, Haffkine Institute, Bombay, is appointed to officiate as Public Health Commissioner with the Government of India, with effect from the date on which he assumes charge of his duties.

Consequent on the grant of leave to Brevet-Colonel S. R. Christophers, C.I.E., I.M.S., Lieutenant-Colonel J.

Cunningham, I.M.S., Director, Pasteur Institute of India, Kasauli, is appointed to officiate as Director, Central Research Institute, Kasauli, with effect from the date on which he assumes charge of his duties.

Lieutenant-Colonel J. W. D. Megaw, C.I.E., V.H.S., I.M.S., Director, School of Tropical Medicine and Hygiene, Calcutta, is appointed to be Inspector-General of Civil Hospitals, Punjab, with effect from the date on which he assumes charge of the duties of that post.

Lieutenant-Colonel T. C. McCombie Young, M.D., D.P.H., I.M.S., an Officer of the Medical Research Department, is placed on foreign service under the Indian Research Fund Association, with effect from the 1st March, 1928.

Major R. H. Malone, I.M.S., officiating Assistant Director, Central Research Institute, Kasauli, is appointed to officiate as Director, Pasteur Institute of India, Kasauli, *vice* Lieutenant-Colonel J. Cunningham, I.M.S.

Major W. O. Walker, M.B., F.R.C.S., I.M.S., officiating Civil Surgeon, Darjeeling, is appointed to act as Civil Surgeon, 24-Parganas, *vice* Lieutenant-Colonel A. Denham White granted leave.

Major T. L. Bomford, M.D., I.M.S., on return from leave, is appointed to act as Civil Surgeon, Darjeeling, *vice* Major Walker, transferred.

Major R. M. Kharegat, I.M.S., an officiating Agency Surgeon, is posted as Medical Officer and *ex-officio* Vice-Consul, Sistan, with effect from the 16th February, 1928.

The services of Major N. Briggs, I.M.S., are placed permanently at the disposal of the Punjab Government for employment in the Jails Department, with effect from the 24th March, 1925.

Captain K. R. K. Iyengar, I.M.S., Assistant Director, Central Research Institute, Kasauli, is attached as a Supernumerary Officer to the Pasteur Institute of Southern India, Coonoor, with effect from the date on which he assumes charge of his duties and until the 11th April, 1928, from which date his services are placed at the disposal of the Government of Madras for appointment as Director of the Institute.

LEAVE.

Brevet-Colonel S. R. Christophers, C.I.E., I.M.S., Director, Central Research Institute, Kasauli, is granted leave on average pay for 8 months combined with leave on half average pay for 2 months, with effect from the 1st April, 1928, or any subsequent date from which he avails himself of it.

Lieutenant-Colonel J. K. S. Fleming, O.B.E., I.M.S., Deputy Director-General, Indian Medical Service, is granted leave on average pay for 3 months and 16 days under Fundamental Rule 100 (a) (i), combined with leave *ex-India* for 4 months and 14 days under Fundamental Rule 100 (a) (ii), with effect from the 24th March, 1928, or date of availing.

Lieutenant-Colonel T. C. McCombie Young, M.D., D.P.H., I.M.S., an Officer of the Medical Research Department on foreign service under the Indian Research Fund Association, is granted leave on average pay for 4 months (including privilege leave for 60 days under military rules) combined with furlough *ex-India* for 4 months, with effect from the 1st May, 1928, or date of availing. His services are replaced at the disposal of the Director-General, Indian Medical Service, with effect from the date on which he proceeds on leave.

Lieutenant-Colonel F. A. F. Barnardo, C.I.E., C.B.E., Civil Surgeon, Serampore, is allowed leave from the 20th February, 1928 (or any subsequent date on which he may avail himself of it) to the 3rd June, 1929, viz., leave on average pay for 5 months and 19 days under rule 81 (b) (i) of the Fundamental Rules, and leave on half average pay for the remaining period under rule 81 (d) of those rules.

Lieutenant-Colonel Alexander Dron Stewart, M.B., F.R.C.S.E., I.M.S., Professor of Hygiene, School of Tropical Medicine and Hygiene, Calcutta, and Officiating Principal, Calcutta Medical College, is allowed leave on average pay for 3 months, with effect from the 16th July, 1928, under rule 81 (b) of the Fundamental Rules,

in combination with the School vacation beginning from the 15th April, under rule 82 (d) of those rules.

PROMOTIONS.

Lieutenant-Colonel to be Major-General.

R. W. Anthony, M.B., C.M., F.R.C.S.E., vice Major-General A. Hooton, C.I.E., K.H.P. Dated 10th January, 1928.

Captains to be Majors.

A. M. Ghosh, M.B. Dated 19th February, 1928.
W. E. R. Dimond. Dated 26th January, 1928.
Ram Chandra Malhotra, O.B.E., M.B. Dated 18th October, 1927.
Henry Caldwell Tait, M.B.E., M.B. Dated 2nd February, 1928.
Jotish Chander Chukerbuti, M.B. Dated 17th February, 1928.

Lieutenant to be Captain.

S. P. Joshi, M.B. Dated 25th May, 1926.

The promotion to his present rank of Major S. R. Prall, M.B., notified in Army Department Notification No. 1031, dated the 20th August, 1927, is antedated from the 18th August 1927 to the 18th February, 1927.

RETIREMENTS.

Colonel C. R. Bakhle, K.H.P., I.M.S. Dated 12th February, 1928.
Colonel K. V. Kukday, I.R.C.P. & S., C.I.E., I.M.S. Dated 15th March, 1928.
Lieutenant-Colonel H. M. Inman, I.M.S. Dated 26th January, 1928.
Lieutenant-Colonel A. W. C. Young, M.B., I.M.S. Dated 29th January, 1928.

NOTES.

THE KAHN TEST FOR SYPHILIS.

A SMALL brochure issued by the Scientific Supplies (Bengal) Co., 29-30, College Street Market, Science Block, Calcutta, at four annas a copy is a reprint of an article by Dr. E. Muir in the *Journal of the Christian Medical Association of India*, Vol. I, No. 5. As readers of our journal well know, Major Lloyd and Dr. Muir have now for several years stressed the importance of syphilis as a contributory factor in causing the persistence and extension of leprosy lesions.

The Kahn test has undoubtedly come to stay, for its reliability appears to be as great as that of the Wassermann test, whilst its technique is simple, easy, and calls for no specially elaborate apparatus. The Kahn test depends upon precipitin reaction, as against complement deviation in the Wassermann test, whilst the former does not need an incubator, and results can be read at a glance.

The chief difficulty in the Kahn test is the preparation and titration of the antigen. This, however, can be overcome by buying standard antigen on the market, as the antigen is stable and keeps well.

The small brochure issued by the Scientific Supplies Co. details the method of carrying out the test, together with a short price list of apparatus and reagents required, and will be of interest to general practitioners who carry out the test.

BRAND'S ESSENCES.

"A good wine needs no bush," and Brand's Essence of Chicken is so well-known and appreciated that it scarcely calls for much comment from us. The firm of Messrs. Brand and Co. have been specialists in invalid diets for nearly ninety years, and during the whole of that time have held the appointment to supply their products to the Royal Household.

Brand's Essence of Chicken is a readily palatable and valuable article of diet in all cases of gastric disorder, fevers, impaired digestion, and severe prostration from any cause. In the tropics it is probably best administered iced in teaspoonfuls; whilst it is a favourite prescription with medical men all over the world. The Indian representative of the firm is Mr. A. H. P. Jennings, Block E., Clive Buildings, Calcutta, who will be pleased to supply literature and price lists.

'SALVITÆ' IN INFLUENZAL COLDS.

It is now generally believed that the micro-organisms which are responsible for influenza and for the common cold are filter passers of *Bacterium pneumosintes* type, and either closely allied or identical. Further, the mildly febrile state associated with the common cold is accompanied by a lowering of the body's alkali reserve, whilst in bronchitis with dyspnoea there is definite acidæmia owing to the accumulation of carbon dioxide in the blood. It is claimed therefore by the American Apothecaries Co., the makers of 'Salvitæ,' that this product is especially indicated in the treatment of and prophylaxis against influenzal colds. Its composition per 100 parts is stated to be as follows:—

Strontii lactas	..	0.30
Lithii carbonas	..	0.15
Caffein et quininæ citras	..	0.80
Sodii-forma-benzoas	..	1.60
Calcii lacto-phosphas	..	0.15
Potassii et sodii citro-tartras	..	59.00
Magnesii sulphas	..	8.00
Sodii sulphas	..	30.00

'Salvitæ,' it is claimed, is an effective diuretic, diaphoretic, and a gentle laxative. It is claimed that its depurative effects check intestinal fermentation, and that it is particularly indicated in deficiency states characterised by fatigue, exhaustion, and acidosis. As a prophylactic it can be taken in small doses daily, whilst in the actual treatment of a cold the dose is a teaspoonful in a glassful of water every four hours.

The Indian agents are Messrs. Muller, MacLean and Co., 8, Old Court House Corner, Calcutta.

Publishers' Notice.

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles will receive 25 reprints *gratis*, if asked for at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions, Advertisements, and Reprints should be addressed to THE PUBLISHERS, Messrs. Thacker, Spink & Co., P. O. Box No. 54, Calcutta.

Annual Subscription to "*The Indian Medical Gazette*," Rs. 16 including postage, in India. Rs. 18 including postage, abroad.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

PURGATIVES CAUSE CONSTIPATION AND PREVENT BOWEL "HABIT TIME."

(A reprint of page 8 taken from the
treatise "Habit Time.")

THE purgative causes a harsh, chemical action in the bowel. It sets up violent irritation and inflammation.

The bowel, being obliged to expel this purgative irritant, whips the muscles into forced activity; the adjacent tissues are drained of moisture, diluting and liquefying the intestinal contents, producing precisely the same physiological effect on the bowel as it would undergo in a defensive effort to eliminate the poisons in diarrhoea. This disrupts every normal functional activity; abnormal faecal consistency is brought about and regular time for bowel movement is impossible.

As a result of this terrific exertion the muscles of the bowel are exhausted and according to nature's rule a period of rest and recuperation must follow. This inactivity may extend for a period of twenty-four to forty-eight hours. During this time accumulation again takes place. Another purgative dose is called for and the whole process is repeated over and over again until the normal, delicate and sensitive mechanism becomes chronically inflamed and thus accustomed to a severe irritant it will not function by any stimulation less severe than the one to which it has become habituated.

This is the way the continued use of the pernicious purgative actually defeats the very object for which it is taken. Instead of benefiting, the purgative aggravates the condition already existing or actually causes sluggish bowels and constipation.

Doctors, everywhere, in their eagerness to avoid cathartics, rapidly adopted paraffin. This, however, has failed, as it has many disadvantages and has apparently been completely replaced by Petrolagar Therapy.

Petrolagar, with its bland, soothing action, is clearly indicated in the various types of constipation including spastic type as illustrated above.

TWO ILLUSTRATIONS TAKEN FROM "HABIT TIME."

PHYSIOLOGICALLY CORRECT PICTURE
OF NORMAL COLON.

SPASTIC CONSTIPATION: PINCHING
DOWN OF THE DESCENDING COLON.

"Habit Time" is a comprehensive treatise on the physiology of the bowel, now in its eighth edition, two hundred thousand copies of which have been issued for the Medical Profession. A free copy will be sent to Doctors in India upon application to Smith, Stanistreet & Co., Ltd., Calcutta; Kemp & Co., Ltd., Bombay; or Spencer & Co., Ltd., Madras.

"Petrolagar" is the trade mark distinguishing the fine emulsion of mineral oil and agar-agar, issued in four varieties: Plain, with Phenolphthalein, Alkaline, and Unsweetened. Manufactured only by Deshell Laboratories, Ltd., London, No. 16.

MICROCEPHALY: A REPORT ON "THE SHAH DAULAH'S MICE."

By C. LODGE PATCH, M.C.,

MAJOR, I.M.S.,

*Medical Superintendent, Punjab Mental Hospital,
Lahore.*

SCATTERED over this continent of superstition and credulity are many shrines of varying repute. At some specific diseases are miraculously cured, at others divers boons are granted. In a land where sons are a social and religious necessity, it is not surprising that there should be a large number of shrines with a reputation for supplying children to barren women. One of these is the ziarat of Shah Daulah.

Shah Daulah was a Mussalman saint who lived during the reigns of Akbar, Jehangir, Shah Jahan, and Aurangzeb. He died in 1676 at the age of ninety-five. He was a broad-minded, philanthropic individual, and succoured all who came to his shrine irrespective of caste or creed. A Hindu, Raja Chattar Singh of Rajour, was one of his disciples. He was especially kind to all dumb animals and had a great influence over birds and deer. He was responsible for the building of several of the bridges across the Chenab and its tributaries. These must have saved numerous lives for floods are frequent in the country around Gujrat, and even to-day it is not uncommon for villagers to be drowned in flood-time. Many miracles have been attributed to him, and these have enhanced his fame, but his name is chiefly associated with the "Shah Daulah's Mice," a curious type of imbecile with a microcephalic head which slopes sharply backwards producing a strangely rat-like appearance.

Certain superstitions and traditions have been handed down regarding these unfortunate creatures. In the earliest times women who came to the shrine made a vow that when the promised child was born, it would be handed over to serve the saint. It is said that this first-born was usually a "chuha" (a rat). After the death of Shah Daulah the vow was amended. The woman was permitted to make a monetary donation in lieu of sacrificing her child. The first child was not necessarily a chuha, but if the mother neglected to pay the money she had promised, a curse befell her and the next child was born a chuha. This curse continued to operate and chuha after chuha would be born until the promise was fulfilled. The alteration in the vow and the superstition can be explained logically. Shah Daulah was a philanthropist, a lover of animals and all weakly subjects.

He also possessed an enormous personal reputation as a saint, so there was no shortage of alms and donations during his life time. The shrine, however, is a poor one and has no *maufi* (land and revenue) attached to it. While Shah Daulah could well have afforded to support the imbeciles presented to the shrine, his successors must have found that subscriptions were not coming in as rapidly as before. A promise of hard cash would naturally be of more use to them than an extra mouth to feed. Indigent parents might continue to dedicate their defective children to the shrine, but the well-to-do classes would prefer to retain their children, imbecile or otherwise, and to escape the anger of the deceased saint by the alternative offering. This suited both parties, and it remained only for the priests to intimidate the anxious parents with the threat that subsequent children would surely be chuhas if the vow were forgotten.

References can be traced to only three medical papers on the subject of the chuhas. The earliest was written in 1868 and the latest in 1903. Theories as to how these creatures are produced have been put forward both by medical and lay writers, but the question of artificial creation has always been left in a state of doubt and uncertainty. A belief which is almost universal throughout the province is that the priests, by means of iron caps, compress the heads of children in such a way that they are reduced in size and exhibit the characteristic shape of Shah Daulah's mice. Even intelligent individuals, some of them doctors, believe that this abominable practice is secretly carried out. This theory will be fully discussed in later paragraphs. Other suppositions are that the microcephalic imbecile is the result of the mating of the hitherto barren mother with a chuha during the course of the period she spends at the shrine in prayer, or in the performance of whatever religious rites have to be carried out. This might account for the first child being born a chuha, but it is a theory which is discreditable to the morals of the woman and of the priests. It is one, however, which is not impossible, although it must be remembered that idiots and imbeciles tend to be sterile, and Sir Frederick Mott has shown that this is a provision of Nature to eliminate the unfit.

A third surmise is that of maternal shock or suggestion on the unborn child. It is not possible scientifically to estimate the effect of certain influences on the pregnant mother, but the belief that such influences can act has been held from the very earliest times. It is recorded in Genesis xxx. that Jacob entered into an agreement with Laban that he would work for him and look after his herds of cattle and flocks of sheep, if he were allowed to take as his share all such cattle and sheep

as were spotted, speckled, and ringstraked with white. "And Jacob took him rods of green poplar, and of the hazel and chestnut tree; and pilled white strakes in them, and made the white appear which was in the rods. And he set the rods which he had pilled before the flocks in the gutters in the watering troughs when the flocks came to drink, that they should conceive when they came to drink. And the flocks conceived before the rods, and brought forth cattle ringstraked, speckled, and spotted." The evidence for this theory is far from conclusive, but, as in the case of Laban's cattle, it is just possible that a pregnant mother may be affected by external influences, and these may have an effect upon the appearance and the destiny of her unborn child. To wit, she might be subjected to the frequent presence of a terrifying chuha coupled with the guilty knowledge of an unfulfilled vow. But no real facts support this theory.

Microcephalic imbeciles are found in all parts of the world who, in appearance, are indistinguishable from the chuhas of Gujrat. A skull is said to be microcephalic when its circumference is four or five inches below the normal. Thus in Europe a skull of 17 or 18 inches would be regarded as microcephalic. Man differs from the lower animals in the relative size of his cranium as compared with the size of his face. Any physical peculiarities which increase the relative size of an individual's face, such as prognathism; or which reduce the relative size of the cranium, such as microcephaly, will tend to give the individual the appearance of an animal. Microcephaly further tends to create this impression of animalism because the skull differs from the normal not merely in size but also in shape. Shuttleworth and Potts observe that such heads recede sharply from the brow, have a pointed vertex, and a flattened occiput so that they show two distinct angles, one at the forehead and the other at the vertex. This is so constant and pathognomic a feature that they do not feel justified in applying the term "microcephalic" to skulls which are merely reduced in size and do not show the typical shape associated with microcephaly. Tredgold goes further and states that typical microcephalics are found with a cranial circumference of nineteen inches or more. He has diagnosed the condition in a skull of twenty-one inches; and adds, "The actual brain capacity is less than a mere circumferential measurement would suggest, by reason of the deficiency being chiefly in the upper parts of the skull."

Eastern imagination has coined the name "chuha," but the similarity of microcephalics to the lower animals has frequently been remarked by Western alienists. Pinel in his "Traite Medico-philosophique sur l'aliendation Mentale" describes a young female idiot

of eleven years who bore a most striking resemblance to a sheep both in her appearance and in her mode of living. Cole and Clouston comment on their similarity to birds. The latter states, "Very typical microcephalics are rare, but, when seen, they make a strong impression. With their bird-like profiles they look so impish and unearthly." Lombroso has described a bird-man, a goose-man, and a rabbit-man, all microcephalics. Dr. Nolan, in the *Journal of Mental Science* for January 1904 gives this amusing description of a microcephalic idiot:

"His physical appearance would have rejoiced the heart of an evolutionist; as *primâ facie* he was a perfect specimen of the simian type. . . H. C. however, was as far below the level of average ape, as the latter is inferior to the highly developed specimen ("Consul") at present, the delight and wonder of a London Music Hall, where, in spotless regulation garb, he discusses with evident appreciation and discrimination the elaborate menu set before him. H. C. if placed before such a meal would have brought his voracious appetite to bear not only on the viands, but on the napery, glass, and cutlery, and by preference would probably try the latter as a *hors d'œuvres*." The tall chuha on the right of the group (Fig. 1) could just as aptly be compared to a sheep, a bird, a rabbit, or a monkey, as to a rat.

The opinion of scientists as to how microcephaly is caused has changed considerably in the last few years. The earliest theory was that it is an atavistic variation, a throw-back to an animal existence: support was lent to this view by the facial appearance of the imbecile. Later, at a time when it was recognised that certain other abnormal skulls owed their deformity to irregular and too early closure of certain of the sutures, it was thought that microcephaly was due to some sort of universal synostosis. On this misconception, Lannelongue performed craniectomy in a number of cases "in order to allow the brain to expand." This operation was found to be utterly useless: indeed, in some cases, the skull became smaller. All modern authorities have now come to the conclusion that the skull conforms to the size of the brain, and not *vice versa*. Stoddart says, "Smallness of the head is due to the smallness of the brain." Shuttleworth and Potts state, "the small skull is merely the envelope of the brain on which the normal development has been arrested, probably about the fifth month of gestation." It would be wasteful for Nature to build an abnormally sized brainbox for an abnormally small brain, and Nature abhors waste, to say nothing of a vacuum. When the occasion demands it, she provides a macrocephalic skull with a circumference of as much as 37 inches to accommodate a hydrocephalic brain, a brain distended with fluid. As a case in point there is in the museum at Marseilles the skull of

Borghini which is 12" high and 36" in circumference. The owner was a four-foot dwarf and a hydrocephalic idiot. A term of contempt for the intellectual powers of a rival, and one which exists down to the present day is, "He is as wise as Borghini!" Tredgold discusses briefly the reasons why science has discarded the earlier theories as to the causation of microcephaly and concludes, "the real truth is that microcephaly is neither atavistic nor accidental, but the result of inherited blight, just as amentia in general. In most of the cases which I have examined morbid inheritance was present. In fact, microcephalics usually come of a pronounced neuropathic

gave an excellent account of himself; said he was a "pir" and prayed at the houses he visited; he stated that twenty-five years ago he had been at the shrine of Shah Daulah and returned to Gujrat occasionally; he denied ever having had sexual intercourse as he was a holy man and above such things. He accepted only food and refused a monetary offering. He was scrupulously clean in his dress and person. He had a very shrewd idea of the prices of food-stuffs, knew that there were sixteen annas in a rupee and eight pice in a two-anna bit, and probably had a greater degree of intelligence than most villagers in the Punjab.

Fig. 1.

stock. Their brothers and sisters are often typical degenerates, and frequently one or more of them suffer from the same condition."

The milder degrees of microcephaly are not necessarily associated with idiocy or imbecility. In perfectly normal individuals the size of the head varies considerably as any hatter will testify. Eugene Talbot, in his "Degeneracy: Its Causes, Signs, and Results," states that Descartes, Foscolo, and Schumann were sub-microcephalic; that Donizetti and the poet Shelley had exceptionally small heads, the latter showing other stigmata of degeneration as well. The grosser degrees of microcephaly, however, are usually (some say invariably), accompanied by a greater or less amount of mental deficiency. The majority of chuhas are incapable of speech, but Peterson observes that, "like an animal the idiot may be intelligent but speechless. The development of language and intelligence is not parallel." A certain number of chuhas can get about the country alone, speak quite well, and take care of themselves. One such was found wandering about the Mall in Lahore and was examined at the Mental Hospital. His cranial circumference was slightly over 18 inches, but in appearance he was a typical chuha. He

The popular belief that chuhas are artificially produced by the priests is strengthened by the fact that in other districts of the Punjab and in Sindh the heads of young children are moulded so that in later years they will conform to certain standards of beauty. The protruding foreheads of the Sindhia women are caused by pressure on other parts of the cranium. In the western parts of the Province, such as Multan, Muzaffargarh, etc., aesthetics demands a flattened occiput, so the mother lays the newly-born infant on its back with its head resting on a brick or a baked tile. This position is maintained for several months, and, if necessary, the limbs of the infant are tied down to prevent it from rolling over on its side. Manipulative and manual pressure are also employed on the back of the child's head in order to obtain the desired result. As a consequence of these, any man from Multan will remove his pagri and exhibit his occiput as a thing of beauty. Such skulls are distinctly brachycephalic. Lyons and Waddell in their "Medical Jurisprudence for India" give the average cephalic index of the Baluchi skull as 88.0, while their average for the other parts of the Punjab where this practice is not carried out is only 73.5. India is

not the only country in which artificial moulding of the head is carried out. It occurs among the North American Indians and in certain savage tribes of Africa; Hippocrates and Strabonius mention the practice in their works, and, in more recent times, Delisle writes of the artificial compression of infantile heads in the Toulouse district of France. He emphasises the fact that no mental impairment is produced by such head-moulding, and of course none can be attributed to the practice in Multan.

The artificial pressure as applied in Sindh, Multan, and elsewhere is localised. It is not universally applied over the whole cranium. Its primary effect is a compensatory enlargement in those parts of the skull which are not subjected to pressure: in the case of the Sindhia women the forehead protrudes, in the case of the Multan skull there is an increase in the transverse diameter which considerably raises the cephalic index. The skull, however, as mentioned above, is a comparatively tightly fitting envelope for the brain, and its size corresponds to the size of the brain enclosed within. While localised pressure during the first few months of life will certainly cause an alteration in the *shape* of the head, no amount of pressure, localised or otherwise, can cause an appreciable reduction in the cubic capacity of the cranium. The only effect that one would expect from any attempt to reduce the *size* of this closed receptacle would be clinical symptoms of compression which would result in death if the pressure were not relieved.

Another effect of pressure on any part of the skull during infancy is the obliteration of the normal bony prominences and landmarks in the area over which pressure had been applied. In the heads of individuals from Multan and Muzaffargarh, the external occipital protuberances are neither visible nor are they easily palpable. Not only were these palpable in the skull of every chuha examined, but all the other bony landmarks could also easily be felt under the scalp. The scalp of microcephalic imbeciles is usually thick and loose, and often thrown into rugose furrows; but an exception was found in the case of the chuha on the right of the group (Fig. 1). In this chuha the scalp was thin and closely adherent to the skull. In the first photograph the frontal eminences stand out clearly, in the second photograph, showing a three-quarter back view, one can distinctly see the external occipital protuberance and also the temporal ridge, which is not ordinarily visible even in a perfectly normal skull. After the fashion of Mohammedans, this chuha's head had recently been shaved, so the bony landmarks are more obvious to the naked eye.

The fiction, however, that chuhas are produced by mechanical contrivances is likely to continue so long as human nature is unaltered.

It is only natural for the mass to cling to a fantastic and sensational explanation when some simpler one would serve equally well. It is only human for the general public to entertain the worst possible opinion of an individual under suspicion. Local gossip whispers that from time to time children have escaped from the shrine and have spread tales of torture by the application of iron caps. This would revive popular interest if ever it showed signs of waning. Thus the ridiculous theory continues from one generation to another, incapable of escape from the vicious circle in which it travels. Psychopathic children with a craving for sympathy and notoriety are found, like microcephalic imbeciles, in every part of the world. But their

Fig. 2.

statements must always be accepted with reserve. During the eighty years of British administration not a single charge of such malpraxis has been brought against the priests at the shrine of Shah Daulah, and any allegations of these criminal practices put forward by a child must certainly have been followed up by the police and found to be without truth or foundation. All records, and the priests themselves, state that children are not admitted to the shrine till they are a few years old. At this age artificial compression would probably be ineffective in producing an alteration, even in the shape of the skull. Moreover, from the point of view of commonsense and expediency, it is impossible to believe that the priests would apply an iron cap or any other form of pressure to the head of a child who could talk and so retail its experiences in evidence against them.

Thus whether one approaches the problem anatomically and clinically or legally and sociologically, the result is the same. The balance of probability is opposed altogether to

the theory of artificial production by mechanical means. The priests, however, do not appear ever to have taken any active steps to contradict or dispute this theory. The reason for their silence is not hard to find. They are astute individuals, and, like cinema stars, have a due appreciation of the value of advertisement. The more mystery that surrounds a shrine, the better will be the business. Perhaps, too, they realise that fewer servitors and more subscriptions will result from a suspicion in the lay mind that they torture their charges.

There is no doubt that a certain number of the chuhas attached to the shrine come direct from their mothers. Whether or not a woman was under a vow to dedicate her child to the shrine, she would recognise that it bore the hall mark of Shah Daulah, the patron saint of such imbeciles, and she would feel that she

kidnapping trade in Jammu and Poonch from which districts a large number of chuhas were received. In the very earliest times all the chuhas were kept permanently at the shrine, but at the time when "The Chronicles of Gujrat" was written, a limited number were hired out to *faqirs* at the rate of from Re. 1-8 to Rs. 2 per month. These returned to the shrine three times a year, at the feasts of Id-ul-Fittar, Id-ul-Zuha, and the Urs or tenth day of Muharram, when melas or fairs were held. The priests state that, nowadays, none of the chuhas is retained for service at the shrine, but all are "on the road," each in charge of its keeper; melas are no longer held at the shrine, nor is there any obligation for the chuhas to return at stated intervals. Chuhas are used solely as beggars, and their commercial value as solicitors of alms is enhanced by the superstition that any woman

Fig. 3.

was performing a meritorious action in handing it over for service at the shrine. The great majority of the chuhas come from the poorest classes, and the upbringing of a congenital imbecile must present a serious economic problem in a land of large families. The population of India is three hundred and twenty millions, and a considerable number of microcephalics must be born each year. Flora Annie Steele in "The Five Rivers" suggests another way in which the supply of chuhas might be augmented, viz., that the priests of the shrine get in touch with the mothers of these abnormal children through agents all over India, that the normal babies who are presented to the shrine are exchanged secretly for the microcephalic infants, and thus the prestige of the shrine is maintained.

"The Chronicles of Gujrat," written a generation ago, alleges that the priests were associated with the *Barda-Faroshi*, or

who refuses a dole to these wretched creatures will incur the displeasure of Shah Daulah and her next child will be born in the form of a chuha.

Arrangements were made for collecting as many chuhas as possible at the ziarat of Shah Daulah, but in spite of a fortnight's notice the priests were able to produce only three real chuhas. They also brought forward four other imbeciles who did not conform to the true microcephalic type, and tried to pass them off as the real thing. They say that chuhas are sent very far afield in these days, and this is probably true, owing to the increased facilities for railway transport and the fact that there is no longer any necessity for them to return to Gujrat from time to time. It would appear also that, in this commercial age, the priests have discovered that other types of imbecile can profitably be used as substitutes for the microcephalic which is associated with the name of Shah Daulah.

COMPRESSION FRACTURES OF THE SPINE.

By E. W. C. BRADFIELD, M.S.,

LIEUTENANT-COLONEL, I.M.S.,

CAPTAIN T. W. BARNARD, M.S.R., F.R.P.S.,

and

R. MAHADEVAN, M.B., B.S.,

Government General Hospital, Madras.

SEVEN cases of "traumatic spondylitis" which were admitted in the senior author's wards during the past year and whose notes have been collected by his House Surgeon, Mr. R. Mahadevan, suggest that compression fractures of the vertebræ are not so rare as is commonly supposed. Obscure back injuries to coolies engaged in lifting heavy bales or to toddy-drawers who fall from a tree directly on to the buttocks are often of this nature. The illustrations are pantograph drawings taken by Captain T. W. Barnard from the original

hospital after nearly 12 months, able to walk and fit for light work.

2. Narayanswami, peon, 30 years, male, Hindu, fell from a cocoanut tree on his buttock a month before admission to the hospital and was unable to get up for a fortnight. Walks with stoop and a rigid back. Prominence in the region of 11th dorsal to 1st lumbar spine. No paralysis of muscles or loss of sensation. X-ray showed fracture of body of 1st lumbar vertebra, wedge-shaped. Left hospital after three months, completely relieved, able to walk and return to work.

3. Lakshmanan, aged 25, male, Hindu, was lifting a heavy log of wood on one shoulder and suddenly felt severe pain in the middle of the back and sides, but did not fall down. Complains of difficulty in movement in the region of 10th dorsal vertebra and tenderness over the spine below the 8th dorsal vertebra. No nervous disturbance whatever. X-ray showed disorganisation of 10th and 11th dorsal vertebral bodies. Albee bone-graft operation.

radiographs and show the bone lesions very clearly.

1. Vadivelu, ryot, aged 18, male, Hindu, fell from a cocoanut tree 30 feet high on to his buttocks, 10 days previous to admission. Complains of inability to walk and pain in both hips. There was pain, tenderness and rigidity over the lumbar spine; no paralysis of muscles or loss of sensation. X-ray showed fracture of the body of the 2nd lumbar vertebra. Left

Left hospital after six months; pain almost completely relieved and patient walks about with comfort.

4. Angamuthu, cooly, aged 35, male, Hindu. A heavy weight fell on his back, complained of pain in the back when walking or standing up, pain and tenderness over the 2nd, 3rd and 4th lumbar spines. No nervous symptoms whatever. X-ray showed compression fracture of the body of the 2nd

lumbar vertebra. Left hospital after five days rest. Refused to stay till complete relief.

5. Subbarayan, cooly, aged 30, male, Hindu. A rice bag fell on his back from a cart two hours prior to admission to the hospital. Pain and swelling (hæmatoma) over the region of all the lumbar vertebræ. No paralysis, no disturbance of sensation. No loss of sphincter control. Pain in the region of the lumbar spines. X-ray showed compression fracture of the 2nd lumbar vertebra. Left hospital after one month. No pain or rigidity of spine.

6. Subramanian, aged 30, male, Hindu. A heavy weight fell on his back two years before admission to the hospital. Had pain in the inter-scapular and shoulder regions. Continuous severe pain in the upper dorsal region but no limitation of movement. Pain most marked in the region of the 3rd, 4th and 5th dorsal spines. No nervous symptoms whatever. X-ray showed fracture of body of 4th dorsal vertebra. Left hospital after ten days with symptoms relieved.

7. Govindan, ward boy, aged 30, male. Other caste. Fell from a tree 30 feet high; could not sit up or walk; pain in the back and tenderness over 2nd and 3rd lumbar spines. No nervous disturbance whatever. X-ray showed fractured body of the 2nd lumbar vertebra. Left hospital after two and a half months. Completely relieved.

Treatment of these patients once the lesion is recognised is easy and simple. An extension applied to both lower limbs and tied to the foot of the bed, which is raised to produce counter-extension by the patient's own body weight, is all that is necessary. In one patient an Albee bone-grafting operation was performed and was very successful, though one is not convinced that a simpler non-operative treatment might not have produced an equally good result.

In previous annual reports the senior author has recorded two patients—both boys—who had a compression fracture of the atlas vertebra following a fall from a height without any cord lesion, and who both recovered completely.

A SIMPLE RAT-TRAP USED BY THE SHAN VILLAGERS OF THE NORTHERN SHAN STATES, BURMA.

By G. G. JOLLY, C.I.E., M.B., D.P.H., D.T.M.,

LIEUTENANT-COLONEL, I.M.S.,

Director, The Harcourt Butler Institute of Public Health, Rangoon.

Two specimens of rat-traps in use by Shan villagers in the Northern Shan States of Burma have been sent me by Major H. F. L. Duckworth, I.M.D., Civil Surgeon and District Health Officer, Northern Shan States. These traps are of great interest because of their

ingenuity and simplicity of construction. They can be made up in any bamboo-growing country at next to no cost because they are constructed solely of bamboo wood and string.

Fig. 1 shows the trap in the "released" position. C is the chamber, a short length of bamboo of from 3" to 4" diameter and about 11" to 16" in length. One end of the bamboo is left open to form the entrance to the trap, while the other is closed by the natural "node" of the bamboo being left in position. In the trap illustrated, which is of fairly thick bamboo, the bottom is flattened down so that the

Fig. 1.

trap will stand by itself on the ground. In another model the natural curve of the bamboo is left and this trap has to be propped up against some adjoining object when set.

B is the trap-door, made of a flat disc of wood which drops down into a slot cut in the upper part of the chamber. The slot is almost $\frac{1}{2}$ inch wide and extends the full width of the bamboo. The door fits loosely into it. On each side of the door a shallow groove is cut to take the string which operates the door mechanism. This string passes through a small hole observable on the side of the trap chamber just below the slot. A similar hole is present on the other side of the trap. At the top of the trap-door there is a small loop of string into which the thick end of the pin A is inserted when the trap is set. Whilst this is the arrangement in the trap illustrated, another model which I have has a small hole

drilled through the projecting upper end of the trap-door to take the thick end of pin *A*.

E is the spring of the trap, made of a bent strip of bamboo wedged at one end into the trap chamber and having the string operating the trap-door passing over the other end, and held in position by a small notch on either side. The tension of the bent bamboo holds the door tightly closed.

D is a bamboo peg which has two notches cut on it. This peg slips into a small round hole in the top of the trap chamber. The lower notch prevents the peg from slipping out, while the thinner end of the pin *A* engages in the upper notch when the trap is in the "set" position.

A is a tapering pin made from bamboo, attached about half an inch from its thicker end, by means of a string, to the upper end of the bamboo spring *E*. In the "set" position this pin stretches across, more or less horizontally, from the loop at the top of the trap-door to the upper notch of the peg *D*.

Fig. 2.

Fig. 2 shows the trap in the "set" position, and a comparison between the two figures will make the mechanism of the trap clear. To set the trap the spring *E* is pressed down and the trap-door raised. Peg *D* is placed in position, so that the lower notch engages with the edge of the hole in the top of the chamber. Pin *A* is then placed carefully in position. The trap-door is now held up by the pin *A*,

while the lower end of the peg *D* projects into the interior of the chamber.

To bait the trap all that is required is to drop a little rice or other bait into the chamber, so that it passes beyond the projecting lower end of the peg *D*. A rat on entering the trap cannot get through to the bait without disturbing the lower end of peg *D*, which dislodges the thinner end of pin *A* from the upper notch on peg *D*, thus enabling the spring *E* to straighten and slam the trap-door shut.

The writer is indebted to Major Duckworth for presenting these interesting traps to the Museum of The Harcourt Butler Institute of Public Health. The traps have been tested in the Institute and have been found highly efficient.

TUBERCULOSIS OF THE BODY AND CERVIX OF THE UTERUS.

By N. GUPTA, M.B.,

Clinical Pathologist, Medical College Hospitals, Calcutta.

THE most frequent site for tuberculosis in the female genital organs is in the Fallopian tubes. Tuberculous salpingitis usually occludes the inner portion of the tube, so that the tubal contents do not gain easy access to the uterine cavity.

When the corporeal endometrium is involved, the tubes are nearly always affected.

It is rather difficult to find tubercle bacilli in vaginal discharges from a case of tuberculous endometritis. If the endometrium is ulcerated and caseous material is being discharged, then possibly tubercle bacilli may be found.

Cases of tuberculous endometritis are rarely diagnosed clinically, and so they escape bacteriological examination of the leucorrhœal discharges.

Curettage of the endometrial cavity is a better method of diagnosis, and it is employed as a routine in the Eden Hospital for such purposes. It is a desirable procedure, as it clears up the suspicion of malignancy for which tuberculosis is often mistaken.

During the past four years a number of cases of tuberculosis of the body of the uterus and cervix have been encountered in the Eden Hospital, and the following are brief descriptions of the conditions present.

Tuberculosis of the cervix is a rare infection. It may be primary or secondary,—the latter being by far the more frequent. Tuberculosis by extension is by no means infrequent in the external genitalia.

In four out of six cases of cervical tuberculosis studied in the Eden Hospital, involvement of some portion of the genital tract above the internal os was recorded. In the other two the condition seemed to be primary in the cervix.

Fig. 1

Fig. 2.

PLATE II.

Fig. 3.

Fig. 4.

Primary lesions in the lungs are the most frequent occurring in tuberculosis, but none of these cases showed any evidence of pulmonary involvement. Pre-existing inflammation in some form is perhaps a predisposing factor, but nothing can be said definitely as to the etiology. No age is immune. Five of our cases occurred during the active sexual life.

Short histories and pathological reports of the cases encountered in the Eden Hospital are as follows:—

Case No. I. Tuberculous Endometritis.—Mrs. H., European female, aged 24 years, admitted in January 1923, for the following complaints:—

(a) An almost continuous sharp pain in the region of the left lower abdomen.

(b) Leucorrhœal discharge.

(c) Scanty irregular menses.

These symptoms began about three years previously. There was no history or physical evidence of tuberculosis in any other part of the body.

Obstetrical History.—No child. No miscarriage. No abortion.

Examination per Vaginum.—One small tumour, the size of a large pea, felt on the right lateral wall of the uterus.

Patient admitted for fibroid of the uterus and dysmenorrhœa.

The uterus was curetted and the curettings were taken for pathological examination.

The shreds of mucosa removed by the curette were particularly friable and of a yellowish colour.

Under the microscope, characteristic nodules with epithelioid and giant cells were seen. There were collections of lymphocytes within the connective tissue, and the uterine glands were hypertrophied, showing proliferation of the epithelium (Fig. 1).

Case No. II. Tuberculous Cervix.—B., Hindu female, aged 40, admitted in July 1921, for the following complaints:—

(a) Blood discharge for a week after a period of amenorrhœa for 2 years.

(b) Pain in the pelvic region for 2 weeks.

(c) Increasing leucorrhœa for several months—rather thick, fetid, glairy material.

No evidence of tuberculosis in any other part of the body could be detected.

Obstetrical History.—Thirteen children, two abortions, last pregnancy ten years back.

14th July, 1921. *Examination per Vaginum.*—Uterus—small, lying anteverted. Anterolateral cul-de-sac, clear. Posterolateral cul-de-sac, fixed. Cervix felt to be swollen and somewhat œdematous. A small polypus projects from the posterior lip.

Inside, the cervix is nodular and hard.

With the Speculum.—A hard nodular lump of the size of a pea was projecting from the cervix. It was vascular and friable and clinically diagnosed as malignancy of the cervix, infiltrating the utero-sacral region.

A wedge-shaped portion of the tumour was removed for diagnosis.

Pathological Report.—Sections show fibrous tissue and benign adenomatous cervical glands and inflammatory changes. Giant cells are present.

Diagnosis.—Tuberculosis of the cervix.

19th July, 1921.—The patient was again examined and the condition found to be the same as before.

21st July, 1921.—The abdomen was opened and the peritoneum was found firmly adherent to the parietes.

On opening the peritoneum the intestines were found studded with miliary tubercles. The tubes on either side were similarly affected and matted together with the surrounding structures.

The cervix was again examined and found to be hard. A portion of it was removed for histological

examination. It cut with a grating sensation and there was no bleeding.

Section (Fig. 2) shows.—The squamous epithelium is intact. Typical tubercles with giant and epithelioid cells are present. There are also collections of lymphocytes in the connective tissue. The clinical similarity of this condition to that of malignancy is noteworthy.

Case No. III.—P., Hindu female, 24 years of age. For four months there had been increasing leucorrhœa. Physical examination did not show evidence of tuberculosis in any other part of the body. Examination of the cervix showed slight ulceration which was purplish in colour. The body of the uterus and its appendages seemed normal. Sections from the cervix showed the usual histological picture of tuberculosis (Fig. 3).

Case No. IV.—C., Hindu female, aged 21, nullipara, complained of leucorrhœa for several months. Menstrual history, normal. No evidence of tuberculosis in any other part of the body. Examination of the cervix showed it to be red and ulcerated and it felt as if it were malignant. Histological examination of a piece of the cervix showed it to be tuberculous (Fig. 4).

Case No. V.—M., Mohamedan female, aged 30 years, nullipara, had irregular menses and leucorrhœa for several months. She complained of irregular fever for some time. Examination showed the body of the uterus about three-fourths of the normal size, lying anteverted and freely movable. There was a large erosion of the cervix. The whole cervix was inflamed and more or less covered with papillomatous outgrowths which bled easily. There was a thick purulent discharge.

Physical examination of the lungs did not show any evidence of tuberculosis, but she had previously had a slight hæmoptysis. Pathological examination of a wedge-shaped piece from the cervix showed it to be tuberculous. Sections showed characteristic tubercular nodules with giant cells. Sputum negative for tubercle bacilli.

Panhysterectomy and bilateral salpingo-oophorectomy was performed. The cervix, the body of the uterus and the tubes were found to be involved.

Case No. VI.—S., Hindu female, multipara, 24 years of age, suffered from amenorrhœa, rather profuse leucorrhœa, and occasional attacks of pain in the groin for 2 years. The cervix was hypertrophied and showed a bilateral tear.

It was soft and bled slightly on being touched. The uterus was somewhat fixed and there was some thickening on both sides. There was no evidence of tuberculosis in the lungs or elsewhere in the body.

Pathological examination of a wedge-shaped piece from the cervix provided the diagnosis. Sections showed characteristic tuberculous nodules with giant cells.

A description of these cases is published on account of the comparative rarity of the condition, and of the fact that an unusual series of them has been met with here during the last five years.

Interesting features are:—

(i) The fact that in none of the patients could any pulmonary involvement be detected on physical examination at the time, although Case No. V had had a hæmoptysis. Their subsequent histories could not be obtained.

(ii) In two of these cases the condition seemed primary in, and limited to, the cervix, Nos. III and IV.

(iii) The difficulty in deciding the diagnosis without resorting to the examination of microscopical preparations of the tissue.

I express my gratefulness to Colonel Leicester, F.R.C.P., I.M.S., Colonel Green-Armytage, F.R.C.P., I.M.S., and also to Major-Shanks, M.D., I.M.S., for giving me all possible facilities.

TICK-TYPHUS AND OTHER SPORADIC FEVERS OF THE TYPHUS GROUP.

By J. W. D. MEGAW, C.I.E.,
COLONEL, I.M.S.,

Formerly Director and Professor of Tropical Medicine,

and

S. SUNDAR RAO, I.M.P.,

Darbhanga Scholar, Calcutta School of Tropical Medicine.

DURING the past ten years there has been a steadily increasing interest in the typhus-like fevers which occur sporadically in many parts of the world. It is now evident that this disease group is of considerable importance, not only because of the frequency with which people are affected, but also because of the difficulties which arise in connection with the diagnosis, and the mystery which attaches to the mode of transmission in most cases.

Some of the outstanding features of several of the recorded fevers of the typhus group are given in the table inserted in this paper; from this it will be seen that there are certain points in which the outbreaks resemble each other, although there are some respects in which they differ from each other.

Typical temperature charts from some of the records are given; these will be of help to those who come across cases of such fevers.

The literature of the subject has become rather extensive and so it is considered useful to give a brief summary of the chief contributions to the subject.

Anticipating the logical sequence of the story, it may be pointed out that there are three definite diseases which belong to the main typhus fever group.

(1) Louse-borne typhus.

(2) Tick-borne typhus (Rocky Mountain spotted fever is the only form which has been thoroughly investigated), and

(3) Mite-borne typhus (Japanese river fever and pseudo-typhoid fever of Deli belong to this group).

There are many other records of typhus-like fevers, most of which deal with sporadic cases of unknown or doubtful vector.

It is necessary at the outset to emphasize the importance of a study of these diseases, Dr. E. W. Goodall in the *British Medical Journal* of 10th December, 1927, writes: "Attempts have been made to differentiate a new form of typhus as a new disease in various parts of the world (India, Australia, the Malay peninsula), and another reason has been urged for the distinction—namely,

that the infection is believed not to be conveyed by lice. But if the mode of spread is to be used as a criterion of distinction, then we had better call milk-borne scarlet fever 'Power's disease' and so on. 'Brill's disease,' and 'tropical typhus' are typhus fevers pure and simple; and it will only lead to confusion to continue the use of the newly applied names."

If we are to accept Dr. Goodall's drastic suggestion we might at once disqualify the Rocky Mountain fever and the Japanese river fever, for both of these diseases show very striking clinical resemblances to louse-borne typhus and nobody has yet proved that their virus is essentially different from that of typhus. But even if Dr. Goodall would not go so far as this, does he seriously suggest that it is unimportant to determine whether a fever of the typhus group is conveyed by lice or by ticks? The nature of the vector is so important in connection with diagnosis, management of the cases and prevention that the differentiation is not a mere academic question, but one of the first class practical importance.

Probably Dr. Goodall will support our contention that all the diseases which show the clinical picture of typhus should be classed in one group—the typhus-fever group—but it is to be hoped that he will not deter workers from attempting to classify the types of the disease in terms of the vector, as this is a very essential factor in the practical management of the diseases.

Brief Note on the Typhus-like Fevers of India.

In the *Indian Medical Gazette* of January 1917 the senior writer described an attack of typhus-like fever from which he suffered in June 1916. The probable vector was a tick which had remained in situ on the patient's body for about twelve hours. The tick had been encountered in the Kumaon Himalayas in a locality in which sporadic typhus-like fever was notoriously common, as had already been shown by Lt.-Col. McKechnie, I.M.S., (1) in 1913. Apart from the Rocky Mountain fever this was probably the first case in which a typhus-like fever was definitely attributed to a tick-bite, although McNaught (2) had incidentally mentioned that Col. Maher suspected ticks of being connected with a similar kind of fever in South Africa.

The publication of this paper resulted in further evidence being brought to notice of the occurrence of typhus-like fever under circumstances which suggested the tick as the vector, and in the *Indian Medical Gazette* of October 1921, a further note was written in which this evidence was given and a suggestion was made that "tick-borne typhus" might be found to be widely distributed in India and in other parts of the world, also

that it might prove to be similar to Rocky Mountain fever and like that disease be conveyed from a rodent reservoir.

Reasons were given in these two papers for believing that McNaught's "para-typhoid fevers" of South Africa, McKechnie's typhus of Bhim Tal and the "twelve days dengue group fever" described by Davies and Johnson(3) in Nigeria belonged to the same class.

At first the fever was regarded as being of the same type as Brill's disease, but further consideration led to the abandonment of this view as Brill's disease had come to be accepted as sporadic louse-borne typhus. It is evident that grave doubts are now being cast on the louse-borne view of the sporadic typhus of the United States, so that the relationship of the Indian fever with Brill's disease is not by any means disproved. In any case the name of a person is hardly an appropriate designation for such a fever, the important question being to assign the fever to its proper clinical and epidemiological group.

In 1924 Major Shettle gave Dr. Roy and the senior author(4) an opportunity of studying a group of nine cases of typhus-like fever which occurred in a military encampment in Saugor in Central India. The patients had not been in contact with each other, they had been camping in the open country in two widely separated encampments in which about 2,000 persons were living. The distribution of the cases was typically of the "chance" type, lice were excluded, the Weil-Felix reaction was completely negative in five and in only two was it positive in dilutions of 1 in 80. In these cases ticks were not actually found though the conditions of life were such that tick-bite was very likely to have occurred.

In another paper(5) in the same number of the *Indian Medical Gazette*, the senior writer discussed seven further cases which had been reported to him by various medical men in India: in three of these ticks had actually been found on the patients' bodies under circumstances which made it almost certain that there was a causal association between the tick-bites and the attacks of fever. Attempts to convey the disease by blood inoculation to guinea-pigs, white mice and monkeys were made in several cases with negative results.

Additional Reports of Typhus-like Fevers from Other Parts of the World.

In the *Medical Journal of Australia* of January 1922, Hone described 16 cases of a typhus-like fever occurring in Adelaide in which there was a mortality of 20 per cent. Lice could not be incriminated, but contact with a wheat flour weevil or a mite-like parasite of corn was suspected though no satisfactory evidence was produced. In later

accounts (*Medical Journal of Australia*, August 1927), Dr. Hone records 80 cases with 5 deaths; the Weil-Felix reaction is usually positive but the reaction may be only 1:100. The indol producing strains of *proteus* X 19 were used. Guinea-pigs were inoculated without any result. Rodents were suspected to be the reservoirs, but no evidence of the insect concerned could be discovered.

Dr. Wheatland deals with a "Fever Resembling Mild Typhus" in the *Medical Journal of Australia* of March 6th, 1926. The cases (38) occurred in the neighbourhood of Toowoomba in Queensland and many other cases are known to have occurred. The Weil-Felix reaction was positive in dilutions of 1:80 to 1:10,420. There was only one death which occurred in a woman 68 years of age. In no case were lice found, it was exceptional for more than one case to occur in a house. Out of 28 male patients 20 were farmers and on all their farms mice were very prevalent. Of the 10 female patients 9 came from farming districts and in all there was a history of mouse infestation. Guinea-pig inoculations were negative. An ecto-parasite of mice was suspected to be the carrier, and as ticks are not known to infest mice the vector would probably be a mite or a flea. Against mites is the complete absence of local sores. Fleas have never been known to convey a typhus-like fever but the possibility of flea transmission should be considered.

In the *Philippine Journal of Science* of September 1915, Schüffner describes a pseudo-typhoid fever in Deli in Sumatra. Schüffner suspected a tick or mite to be the vector; the disease is now regarded as being mite-borne by the *Trombicula deliensis*. In most of the cases there was a local ulcer and lymphangitis. In the *American Journal of Tropical Medicine* of November 1923, Maxcy and Havens(6) described 11 cases of typhus-like fever with positive Weil-Felix reactions in Alabama. The cases were sporadic, no lice could be found on the persons affected, the season of prevalence was the summer, autumn and early winter months, not the cold season.

In 1925, Dr. William Fletcher(7) of Kuala Lumpur described 18 cases of typhus-like fever; 5 were severe but none was fatal. There was no evidence of person-to-person infection. The persons attacked were chiefly Punjabi cattle-keepers or Europeans living in camp. Lice could be excluded in the cases of the Europeans. The Weil-Felix reactions were very interesting; all were positive, though some only in low dilutions, to a strain of *proteus* X 19 from the Lister Institute. Guinea-pig inoculations were all negative.

Dr. Fletcher has seen many cases of the same kind of fever since writing his first note on the subject. In one article he described 65

cases with 5 deaths. Serologically these cases fall into two distinct groups:—

1. Group K consist of cases which agglutinate the "Kingsbury" or non-indol producing strain of *proteus* X 19 and are negative to the indol producing strains such as the "Warsaw" and "No. 67" strains.

2. Group W cases are negative to the "Kingsbury" strain and positive to the indol producing strains.

There are certain epidemiological differences between the cases of the two groups, which suggest to Dr. Fletcher that the vector may be different. Dr. Fletcher suggests the name "tropical typhus" for these sporadic cases of typhus-like fever. In the *Report of the Institute for Medical Research* of Kuala Lumpur for 1926, Dr. Fletcher refers to some cases of tsutsugamushi or kedani fever which he has seen on the 15th day; in every case there was a characteristic primary ulcer and a bubo, the fever lasted from 20 to 26 days in the patients who survived.

Animal inoculations and the Weil-Felix reactions were negative, except that one patient showed agglutination to Wilson's *B. agglutinabilis* in dilutions of 1:120. *B. agglutinabilis* was also agglutinated with the serum from cases of tropical typhus of the W group, but was negative to those of the K group.

In 1925 Dr. Anderson(8) of the Kenya Colony described a very similar disease to which he gave the name "pseudo-" or "paratyphus." Cases occurred sporadically every year in the rainy season at a height of over 5,000 feet. Only one death was known to occur.

Early in 1927 Dr. Spencer(9) reported a case of typhus-like fever from Norfolk, Virginia. The fever started ten days after a bite from a tick which came from a calf hide. There was redness, swelling and a small ulcer at the site of the bite. The Weil-Felix was negative and so was guinea-pig inoculation.

The tick was not preserved but was believed to be *Amblyomma americanum*. Others who were bitten by ticks did not suffer.

In the *British Medical Journal* of the 3rd December, 1927, there is a report of cases of

"Brill's Disease" in and round Marseilles seen by Drs. Olmer, Boinet and Pier (*Bulletin de l'Academie de Medicine*, October 4th, 1927). The cases were nearly all sporadic. No lice were found and the Weil-Felix tests were negative. In most cases there was a small black scar suggesting an insect bite. There was congestion of the throat, sometimes with small ulcers of the mucosa. Meningism was common. Only one death occurred apparently in more than 50 cases.

Just before sending this to the press we have seen a further note on this disease by Burnet and Olmer in the *Archives de l'Institut Pasteur de Tunis*, Tome XVI, No. 4, of December 1927 under the heading "La Maladie de Marseille." The question is raised whether it is mild typhus (Brill's Disease) or "tropical typhus."

The disease has been known in Marseilles and the Midi of France since 1922. A relationship with the "fevre boutonneuse" of Tunis was suggested by Nicolle.

The rash extends to the face, there is often pharyngitis, rarely conjunctivitis, there are local papules or scars associated with adenitis, suggestive of a bite by an insect.

The disease is common in the summer and autumn, not in winter; there is no evidence of person-to-person infection and lice have been excluded.

The Weil-Felix reaction was thoroughly tested against numerous strains of the *proteus* X 19 and was almost invariably negative. The strain used by Olmer gave negative results in 42 cases; this strain when tested against the serum of a case of typhus responded at once in a dilution of 1:500 and so was proved to be agglutinable. In three cases conflicting results were obtained using 8 strains: one of these cases was negative to all on the 10th day; another was positive in dilutions of 1:125 or over to 5 strains and negative to 3 on the 20th day of convalescence; the third was positive to 7 out of 8 strains on the 3rd day of apyrexia. All the other cases were negative. The following are the examples of the variations in agglutination response found by the authors:—

Subject.	Dilution.	Paris Strains.					Marseilles Strain.	Constantinople Strain.	Paris Strain.
		0 X19	H 2X	H X19	X19	Job X19			
A On the 3rd day of apyrexia.	$\frac{1}{250}$	++	++	++	++	++	+	0	+++
B On the 20th day of convalescence.	$\frac{1}{250}$	+++	..	++	±	0	0	+++	+++
C On the 10th day of disease.	$\frac{1}{125}$	0	0	0	0	0	0	0	0

PLATE III.

Fig. 1.—Gunner K. 13th day of disease.

Fig. 2.—Gunner K. 13th day of disease.

Fig. 3.—Gunner K. 13th day of disease.

PLATE IV.

Fig. 4.—Gunner K. 13th day of disease.

Fig. 5.—Mr. C. 10th day of disease.
(Dr. Ghosh's case.)

Fig. 6.—Mr. C. 10th day of disease.
(Dr. Ghosh's case.)

The guinea-pig inoculation experiments were carried out with great thoroughness; sub-inoculations were made from brain tissue of the first series of guinea-pigs with negative results in both series. Guinea-pigs which had been inoculated from three febrile patients and showed no febrile reaction were tested later by inoculations with typhus virus and showed the typical febrile response.

The authors do not consider that the problem has been solved and ask for further investigation. They give useful hints as to methods which ought to be followed in experimental and epidemiological work on the subject.

In the *U. S. Public Health Report* for June 18th, 1926, Maxcy reported that 209 cases of endemic typhus had been diagnosed in Alabama with a mortality of 2 per cent. and a positive Weil-Felix in 93 per cent. The disease was regarded as typhus, but it was suspected that the louse was not the vector. In another report in December 1926 (*U. S. Public Health Report*, No. 52, Vol. 41, December 24th, 1926) Maxcy discussed the epidemiology of this disease and commented on the facts as follows:—

(1) The distribution is scattered in place and time.

(2) Males are attacked twice as frequently as females.

(3) Negroes escape.

(4) The incidence is much greater in the summer and autumn than in the winter and spring.

(5) Persons engaged in food depôts, groceries, feed stores and restaurants are exposed to a distinctly increased risk of infection.

(6) The disease attacked those who earned a reasonably good livelihood and seldom affected the unskilled labourers or unemployed.

(7) The poor and uncleanly were not specially attacked, most of the victims were cleanly in their habits.

(8) There was very rarely any history of association with an infected person; and multiple cases in the same household very rarely occurred.

(9) The disease was not associated with louse infestation.

Maxcy raises the question whether there may not be a rodent reservoir and an arthropod vector other than the louse. Rats and mice are suspected as the reservoirs, fleas, mites and ticks as the vectors.

Further Observations on Indian Typhus-like Fevers.

The following cases and groups of cases have not been published hitherto, with the exception of a few which were reported in such a way that due credit was not given to the medical men who recorded them. We

are indebted to those who have so kindly forwarded reports of cases.

Cases Reported by RAO BAHADUR CAPTAIN P. KRISHNASWAMI, M.B., C.M., D.M.O., Kristna Dist. (Madras).

Dr. Krishnaswami has sent us an interesting record of 9 cases of typhus-like fever (Charts Nos. 1—9) which occurred among about 1,000 men of the Gurkha Rifles while marching through the hill jungles of Narsapatnam in the North-East of the Madras Presidency. The following is a summary of Dr. Krishnaswami's report. The cases obviously belonged to the typhus group but the Weil-Felix reaction was quite negative in five cases, and was positive up to a dilution of 1:100 in the only other case in which the test was made. The Widal reaction and blood cultures were negative in all the cases. One patient was strongly positive to the Wassermann test, another was moderately positive, the rest were negative. All these tests were carried out at the King Institute, Guindy, by Lt.-Col. J. Cunningham, I.M.S. There was no evidence of person-to-person conveyance of the disease. Lice were excluded, no ticks were found, but the conditions were such that tick-bite was very likely to occur. The rash was similar to that reported in other groups of sporadic typhus-like fever in India. In the earlier cases the rash was not noticed till the 9th or 10th day and there is no record of the order of its appearance on the different parts of the body. Little importance is attached to the failure to observe the rash during the earlier days of the fever in these cases, as the patients were dark skinned and the nature of their illness was not at first suspected.

In the last three cases the rash was noticed on the 4th day in two and in the 6th day in one. In these patients the rash first appeared on the extremities and spread to the trunk. It was a discrete macular or papular rash which strongly suggested a syphilide in two of the cases. The note by Lt.-Col. J. Cunningham, I.M.S., and Dr. Theodore in the *Indian Medical Gazette* of October 1924 refers to these cases. The following extracts from this paper are of interest.

"The distribution of typhus fever in India is so imperfectly known that the occurrence of cases in a locality where the disease has not yet been previously recognised is worthy of record. Between the beginning of February and end of March this year 8 specimens of blood were received at the King Institute from the Medical Officer in charge of the Base Hospital, Narsapatnam, the base for the Futuri operations which have up till recently been carried on in the Agency Tracts of this Presidency. All of these specimens were negative to the usual examinations for malaria and fevers of the enteric group. The eighth case, however, gave a well marked Weil-Felix reaction, being positive in 1:100. This case was thus proved to be one of typhus fever. As no case of this type of fever has so far

as we are aware been previously reported in this Presidency, we requested Dr. Kesavaswamy to give us further information as to this particular case. His description of the symptoms together with the temperature chart which he kindly forwarded to us are typical and leave no doubt as to the correctness of the diagnosis. He also gives the following additional notes on the outbreak which are of interest.

to whether the disease has spread to the civilian population, but no cases have been reported from this source up to the present. It is of interest to note in this connection that the Agency Tracts where these cases have occurred have been free from relapsing fever so far as we are aware; whereas in the Nilgiri Hills where relapsing fever is raging at present no evidence of typhus fever has been obtained, although we have examined

Temperature and Pulse Charts of Typhus-like Fever Cases of Narsapatnam.

9. P.R. Age 21.

Before the Assam Rifles came to this Agency about the end of January 1924 this type of spotted fever was unknown in the Agency. Eight cases with exactly similar clinical pictures were admitted to this hospital between 12th February, 1924 and 29th February, 1924. The first case was that of a Sub-assistant Surgeon attached to the Assam Rifles. Of the nine cases (including the one under report) five were among the Assam Rifles, two among Sub-assistant Surgeons attached to the Assam Rifles, one (the present case), is an orderly attached to a Sub-assistant Surgeon (who was not attacked). In all cases the rash disappeared about the 25th day. Convalescence was established between the 15th and 18th day of the illness.

The disease was therefore obviously imported by the Assam Rifles from Assam. There is no information as

the sera of many cases of fever in whose blood no spirochaetes could be found at the time of examination.

It would appear that even in the hill tracts in this country relapsing fever and typhus fever do not occur in association with each other.

We do not accept Lt.-Col. Cunningham's suggestion that the disease was imported from Assam. It is more likely that the infection was one of the animals of the jungle through which the troops were marching, and therefore the absence of association with relapsing fever is not surprising.

Case Reported by DR. C. M. SCOTT, M.B.

A case was personally reported by Dr. C. M. Scott, M.D., of Rutlam, Central India (altitude 1,800 feet) in October 1924. The rash appeared on the 3rd or 4th day, first on the arms, then on the whole body including the palms, soles and even the scalp. At first the rash was macular, fading on pressure, staining persisted for several weeks. There was headache, sore throat, rigors and sweats. The fever was remittent, it started suddenly and lasted sixteen days ending by lysis. No lice or other insects were found and no other cases were known to occur in the locality. Dr. Scott was the patient himself.

Case Reported by LIEUT.-COL. T. E. FIELDING, R.A.M.C.

A case was personally reported by Lieut.-Col. Fielding. The patient was a European, aged 20, a gunner in the Royal Field Artillery lines in Secunderabad (altitude 1,830 feet). The date of onset was 21st November, 1924. The rash was noticed about the 3rd day on the chest and abdomen. It spread to the arms, legs, hands, feet and face. It was roseolar, macular, not definitely papular, and staining persisted at the sites of the spots for about 5 weeks. There was subacute conjunctivitis, headache and pains all over the body. The fever had a gradual onset, it lasted 15 days and ended by lysis.

The patient had been bitten about six days before the onset by "some insect" in the horse lines. There were no other cases in the locality. Blood culture was sterile.

Case reported by DR. C. E. S. NARMAN, F.R.F.P. & S., D.P.H., L.A.H., and DR. C. S. RAMCHANDRAN, M.B., B.S.

Dr. Norman and Dr. Ramchandran have reported a case in the *Indian Medical Gazette* of May 1925 in an elderly European in Trichinopoly on January 2nd, 1925 which appears to be of sporadic typhus-like fever. The eruption appeared about the third or fourth day, first on the legs then the abdomen and arms, finally on the forehead. There was vomiting, severe joint pains, suffusion of the eyes, slight leucocytosis. The spleen was enlarged. The fever lasted about 14 days. No history of tick-bite nor of association with any other person suffering from a similar disease was obtained.

Cases reported by LT.-COL. J. MCPHERSON, I.M.S., Residency Surgeon, Bangalore.

A European male, aged 58 (Chart No. 14), living in Bangalore (altitude 3,000 feet). The onset was on the 19th November, 1925. The type of the rash and the course of the fever were quite typical. Blood cultures (10th day) were sterile and the Widal (12th day) was negative. The patient was free from lice: he had been bitten by ticks 14 days previous to the onset while in camp.

Col. McPherson in an accompanying letter reports that he had seen two other cases in which he believes tick-bite to have been responsible, one was a European lady in Peshawar who had fever for 12 days with a maculo-papular eruption all over the body, and "pink eye." The Weil-Felix and Widal reaction were negative, no parasites were found. The patient had been bitten by ticks in Malakand shortly before the onset of the fever, one of the ticks had to be extracted forcibly.

The other patient was a European male (Mr. J. G. L., r.c.s.), in 1909-10 in Baghdad who had a spotty fever which he attributed to ticks which had bitten him when out shooting. The ticks were seen by Col. McPherson "like red pepper grains" and were recognised microscopically as ticks, but the species was not identified. In the above cases louse infestation would be exceedingly unlikely. Col. McPherson also reported a case in a young police officer who had a similar attack "like a mild typhus but not typhus clinically" (Col. McPherson has seen a number of cases of typhus in Peshawar). There was no history of tick-bite in this case.

Case reported by MAJOR C. S. P. HAMILTON, R.A.M.C., Jhansi.

A case was reported by Major Hamilton, R.A.M.C. The patient was Capt. A. E. C., a young European male (Chart No. 15), who was attacked on the 2nd January, 1927; he had been shooting for 13 days in the jungle near Mut-Kuli in the Central Provinces (altitude 3,500 feet), up till 4 days before the onset. The rash appeared on the 3rd day on the abdomen, spreading all over the body, it was profuse, maculo-papular and roseolar, staining persisted after the fall of temperature. There was headache, pains in the joints and all over the body. The course of the fever is seen in the chart. The Weil-Felix test on the 6th day was negative, the pulse was relatively slow and there was no obvious leucocytosis, the differential count on the 6th day being:—Polymorphonuclears 68 per cent., lymphocytes 30 per cent., large mononuclears 1 per cent., eosinophiles 1 per cent.

No lice or other insects were reported, but the conditions under which the patient had been living before the onset are strikingly similar to those of the case in which ticks were found.

Case reported by CAPT. N. M. P. DOTIVALA, I.M.S., M.O., I.S.H., Saugor.

Capt. Dotivala, I.M.S., reported a case which occurred in an Indian driver of the 15th Battery, R.F.A., in Dhana Camp near Saugor where several cases had occurred during the previous year (Chart No. 10). The date of onset was 17th January, 1925. The rash, course of the fever and symptoms are very similar to those of the cases reported in the *Indian Medical Gazette* of February 1925. The Weil-Felix reaction was negative, the total leucocyte count was 6,200 on the 12th day. Guinea-pigs were inoculated with blood on the 8th day of the illness, but the results were negative. Lice were found on his body. There was no evidence of association with any other case of the disease, but there was another case in a European gunner at the same time—see next report.

Case reported by LT.-COL. F. B. SHETTLE, I.M.S., S.M.O., Saugor.

Lieut.-Col. Shettle, I.M.S., who collaborated in the investigation of the previous series of cases in Saugor (*Indian Medical Gazette*, February 1925), reported another case in a European gunner of the 40th Battery, R.A., on the 18th January, 1925, at the same time as the above case (Chart No. 11).

This case was obviously of the same kind as the others already reported and so a detailed description is unnecessary. The locality was the same as in the previous case. Lice were found on his body but no association with other cases could be discovered. He had helped to carry a buck which had been shot in the jungle shortly before the onset so that he was obviously exposed to the bite of ticks or other arthropods of the jungle. The Weil-Felix was negative (day of disease not recorded). The Widal was + at 1 : 250 on the 4th day against the typhoid and para B organisms and ± at 1 : 150 against para A.

An organism was isolated which was at first regarded as a contamination, but later was reported as "para B." This is the only case out of a large number in which any evidence of typhoid group infection was found, although a very thorough investigation was made. The result must be regarded as unexplained.

Case reported by DR. D. N. ROY, and DR. S. SUNDAR RAO.

Gunner K., European male, aged 20, was attacked on the 30th January, 1926, in Dhana Camp near Saugor from which several other cases have previously been reported (Chart No. 12 and Plates I-IV). Details are unnecessary as the case was quite typical in every respect. No lice were found. No history of tick-bite

was obtained, but the conditions in the camp were such that bites by ticks or other arthropods of the wilds were likely. The Weil-Felix was negative. Two guinea-pigs were inoculated with no obvious result. Another case reported in the locality could not be investigated, but there was no association between the two; the second patient was a European lady who was attacked on December 25th. She was said to have nursed her dog which died of distemper.

Case reported by DR. S. SUNDAR RAO.

Lance Brigadier B., 40th Battery, European, aged 25 (Chart No. 13), was attacked in Chitora Camp near Saugor on the 26th January, 1927. He had been marching by road from Jubbulpore to Saugor from the 11th till the 19th January and from the 19th till the 26th he had been in the camp. The case was quite typical and was the only one among 2,000 men who were in camp. No lice were found, and no association with any other case was detected. On the 9th day the Weil-Felix was negative; on the 16th day it was also negative; on the 21st day the following reaction was found:—

Strain 67 (Kuala-Lumpur) ..	+1 : 160	(This was the strain previously used in all the tests.)
Kasauli Strain ..	±1 : 80	

Kingsbury (Kuala-Lumpur) Strain ..	±1 : 40
Warsaw Strain ..	±1 : 40

This represents the highest agglutination found in any of the sera which were examined either at the Calcutta School of Tropical Medicine, the Haffkine Institute, Bombay, or the Enteric Convalescent Laboratory, Naini Tal. The lateness of the development of the agglutinins is notable; it will be necessary in future cases to test against various strains and up till a month from the onset.

Case reported by LT.-COL. M. R. C. MACWATERS, I.M.S., Civil Surgeon, Naini Tal.

Lieut.-Col. McWatters in the *Indian Medical Gazette* of May 1927 in a paper in which by an unfortunate mistake was attributed to Dr. R. N. Bannerji described two cases of typhus-like fever, (a) one which occurred in a boarding school in Naini Tal. Clinically this resembled true typhus but no epidemiological data were available except that no lice were found. (b) A European male, aged 64, from Naukatchia Tal near Bhim Tal. This gentleman had lived for several years in the area which is believed to be endemic for tick-typhus, no lice were found, he was negative to the Weil-Felix test. He died on the 13th day of the illness. A possible clue to the source of infection was that the daughter of an Indian employee had "typhus" just before his illness which occurred in early September. It is probable but not certain that both of these patients belong to the group of typhus-like fevers conveyed by ticks.

In a personal communication in January 1927, Col. McWatters informed the senior author that the Medical Officer of Bhim Tal had seen numerous cases of typhus-like fever in Bhim Tal and Sat Tal in 1925 and 1926. Most of the patients lived near the lakes which are about 4,500 feet above sea-level: he reported that the infection sometimes appeared to spread from person to person in the affected houses. He also reported that ticks were uncommon, but we are able to assert that human beings are frequently bitten in this locality; both of us have been bitten by ticks in the neighbourhood, one of us twice although the stay in the place was a matter of hours only.

We have recorded exceptional cases in which several persons in the same house were attacked, and the possibility of the virus being capable of communication by lice as well as ticks was mooted (see *Indian Medical Gazette* of February 1924).

The distribution of the disease in Bhim Tal and Sat Tal is essentially sporadic, but every now and then

there is a house outbreak and the abundance of lice in the locality would greatly favour the occurrence of the exceptional house outbreaks if the virus were capable of conveyance by lice as well as ticks.

Case reported by MAJOR W. O. WALKER, I.M.S., Civil Surgeon, Darjeeling.

Mr. P. J. K., aged 42, was attacked in Darjeeling on the 15th June, 1927 (Chart No. 16). The rash appeared on the 5th day, first on the abdomen, then on the limbs and rest of the body including the face and palms. It persisted after the fall of the temperature. Cultures and the Widal reaction gave negative results.

The patient had been bitten by a tick 5 days before the onset while in Kalimpong (altitude 4,000 feet) in the Darjeeling district.

Case reported by CAPTAIN JAMES DOYLE, I.M.D., Civil Surgeon of Balaghat, Central Provinces.

A European official had been shooting in the jungle near Padrigunj Railway station (altitude about 2,000 feet). This place was about 150 miles from Jubbulpore in the Central Provinces.

The date was during Christmas holidays, 1927-28 (presumably December 24th, 1927, till January 2nd, 1928). During this time he found two ticks fastened on his body. The onset of the fever was on the 3rd January, 1928. A few spots were seen on the 4th day of the disease, by the 7th day the spots were profuse and well marked over the body, arms and legs.

Lieut.-Col. Tarr, I.M.S., Civil Surgeon of Nagpur, was called in consultation on the 9th day of the disease and diagnosed "tick-typhus." The fever lasted 21 days (Chart No. 17). The patient was never seriously ill, he was depressed at times.

Malarial parasites were reported to have been found in the blood on the 2nd day and quinine bihydrochloride was given in doses of 20 grains daily, but apparently with no effect on the fever. If malaria really existed it is impossible that it could have been the cause of the fever.

The interesting points in connection with this case are:

(1) The association with a tick-bite about 7 days previous to the onset.

(2) The locality is the same as that in which two other cases occurred in which tick-bite was known to have occurred (Ref. *Indian Medical Gazette*, February 1925).

(3) The disease is now being recognised, as Lieut.-Col. Tarr apparently had no hesitation in making the diagnosis of tick-typhus. Captain Doyle adds that ticks are known to bite human beings in the jungle of Balaghat district during the winter season.

He reports that another European in the neighbouring Seoni district was infected under the same conditions in the previous year and that he has seen six cases altogether during his service.

A Case reported by DR. G. GHOSH, M.B., B.S., D.T.M., Lukergunj, Allahabad.

This report is in Dr. Ghosh's own words.

"Patient Mr. C. Anglo-Indian, male, aged 35 years, suddenly took ill on Monday afternoon, 5th September, 1927, when he returned from his office. He got fever and complained of terrible pains in the small of his back and legs. For a few days before his illness the patient felt languid with severe headache and pains in the legs. On Tuesday the temperature was about 101°F. On Wednesday the fever seemed higher and on Thursday it rose to 104°, and a rash appeared on his chest and back; he was sent into the European Civil Hospital, Allahabad, as a suspected case of small-pox, the same evening.

During the first few days of his illness the patient used to get repeated attacks of shivering and used to sweat profusely every 4 hours or so.

Condition of the patient on admission (8th September, 1927). General condition—shocked, temperature about 105°F. or comatose, complained of severe headache and pain all over the body. His eyes were red and congested.

Alimentary System:—

Tongue—slightly coated.

Bowels—constipated; no tympanites.

Polymorphs	54%
Lymphocytes	42%
Large mononuclears	3%
Eosinophiles	1%

(c) Total white blood cell count—

11,600 per c.mm.

(d) Widal reaction serum agglutinating *B. typhosus* in dilution of 1 : 80. Negative against *B. paratyphosus* A and B.

(e) Weil-Felix reaction. Blood taken on 14th

Temperature and Pulse Charts of Typhus-like Fever Cases.

10. S.S. AGE 23

11. G.R.P. AGE 22.

12. B.K. AGE 20.

13. G.W.B. AGE 25.

14. C.W.G.M. AGE 58.

15. A.E.C.

16. P.J.K. AGE 42.

17. CAPT. DOYLE'S CASE. (Balaghat C.P.)

Localities—10-11-12-13, Saugor C. P.; 14, Bangalore; 15, Mut-Kuli: Pachmarhi;

16, Kalimpong: Darjeeling.

17, Balaghat, C. P.

Spleen and liver—not palpable.

Slight pharyngitis present.

Respiratory system—no signs of bronchitis.

Circulatory system—nothing abnormal.

Blood Examinations:—

(a) No malarial parasites found.

(b) Differential count—

September, 1927, and 28th September, 1927, and sent to Kasauli for this test. Report negative. (+ 1 : 10 ± 1 : 20 against *B. proteus* X 19 indolgenic strain; ± 1 : 10 against *B. proteus* X 19 non-indolgenic strain.)

Urine Examination:—

Colour—dark brown.

Sp. gravity—1,012.

Reaction—acid.

Albumen—nil.

Sugar—nil.

Nervous system.—The patient seemed to be nervous. He complained of severe headache and pains all over the body. He could not sleep for a few nights on account of pain. He was complaining of extreme weakness.

The course of the fever is shown by the chart (Chart No. 18).

18. Mr. C. Age 35.

18. Allahabad.

Rash.—The rash appeared on the 4th day of the disease on the chest and back at first and then gradually appeared on the abdomen, extremities and forehead. The spots were like red papules at first, fading on pressure during the first two days. Afterwards they became dull red in colour and did not fade on pressure (Plate Nos. V and VI). Some of them became distinctly petechial in character. About the 12th day of the disease, they became brownish red in colour and some of them began to disappear. Most of the rash on the arms and forehead had disappeared, but those petechial spots were as big as 3/4 inch in diameter.

The patient left the hospital on 1st October, 1927. He was seen on the 10th October, 1927, i.e., 20 days after the temperature had come down to normal. Marks of rash on the arms and forehead had disappeared but those on the legs and feet were still visible but were fading.

A few other points about the case:—

(1) The patient gives a history of having inoculation of T.A.B. vaccine.

(2) No ticks or lice were found on his person when he was in the hospital.

(3) On being questioned, he gave a history of being bitten by an insect about 10 days before the onset of fever. He went out shooting and also fishing in the jungle of Meja Road—a place about 15 miles from Allahabad and it was there that he was bitten by an insect on the nape of his neck. He mentioned to his wife about the bite. The bite was rather painful but he forgot all about it afterwards. No mark at the site of the bite could be detected when he was in the hospital, i.e., about 15 days after he was bitten."

Note by DR. S. SUNDAR RAO, on an Investigation of Fevers in Bhim Tal and Sat Tal in 1925.

I visited Bhim Tal, Sat Tal and the adjoining villages of Dhungilla, Pande and Bhag-tora in the Kumaon Hills (elevation 4,500 ft.) during the months July to October and during my investigations there I collected the histories of 43 cases of fever which were probably cases of typhus-like fever. But as no thorough examination of all these cases was made, it could not be asserted that all of them were really cases of typhus-like fever. The cases were mostly sporadic in occurrence. Out of the 43 cases mentioned above, the blood was examined for parasites and a differential leucocyte count made in 15 and a full

examination was made of 8 cases. Animal inoculations were also carried out with negative results. Of the 8 cases which were investigated, it was found that there was a definite infection with typhoid in two cases, with paratyphoid "A" in one, and typical typhus-like fever in another (positive Weil-Felix 1 : 80); the remaining 4 cases are possibly cases of typhus-like fever. This shows that there is a likelihood of other fevers being mistaken for typhus-like fever (which certainly occurs in this area), as infection with typhoid, paratyphoid, and malaria are quite common in this area during this season.

That typhus-like fever is common here is well known. I quote from a letter I received from Dr. Gajendra Thapa, L.M.P., Medical Officer-in-charge, Bhim Tal Dispensary "I heard that one of my predecessors died of typhoid fever, but I think he had typhus (Bhim Tal fever). This year we had 11 cases of this (Bhim Tal fever) and of these only 2 patients gave a history of tick-bite within 21 days of getting fever."

I may mention here that it is not always that people are aware of the presence of a tick that has attached itself to them, especially as it attaches itself so unnoticeably and without causing the least feeling of pain or discomfort, even when it buries itself in the host's body. The following instance may be of interest in this connection. A geologist friend of mine who returned from the Assam jungles after a stay of a few days had got on him two ticks, which he had not noticed for over 17 days in spite of the fact that he was having his daily bath. When this can happen to a scientist it is not surprising that most of typical tick-typhus cases give no history of tick-bite if we rely only on the evidence given by the patients.

Localities in which typhus-like fever has been found to follow tick-bite.

The following are the areas in which a typhus-like fever has been observed to occur within a few days of the bite of a tick.

1. The Rocky Mountain fever—In the case of this disease a tick has been proved to be the vector.

2. Indian cases.

(a) Near Sat Tal in the Kumaon Himalayas one case.

(b) Naraingunj in Eastern Bengal—one case.

(c) Balaghat in the Central Provinces.

There were three definite cases from this locality.

(d) Bangalore. One case.

(e) Malakand. One case.

(f) Kalimpong near Darjeeling. One case.

3. Mesopotamia—A case in Baghdad.

All the cases from India and Mesopotamia have been described in the papers by the senior writer.

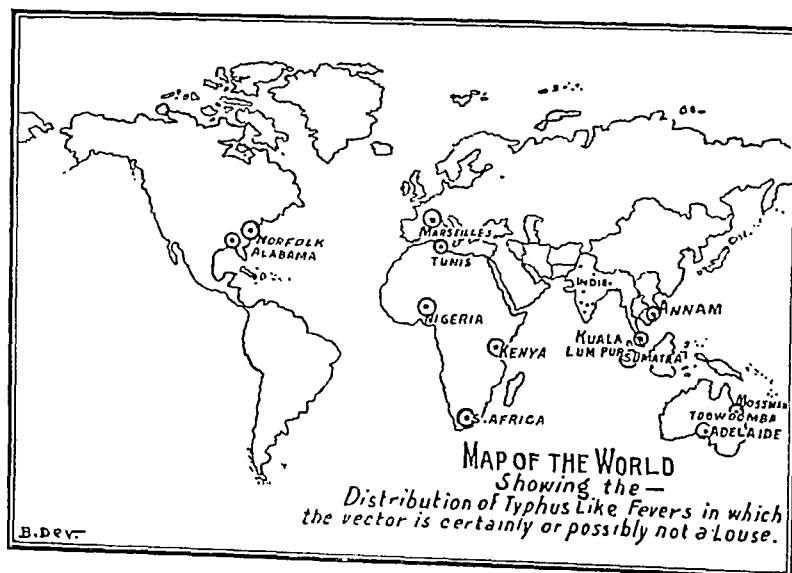

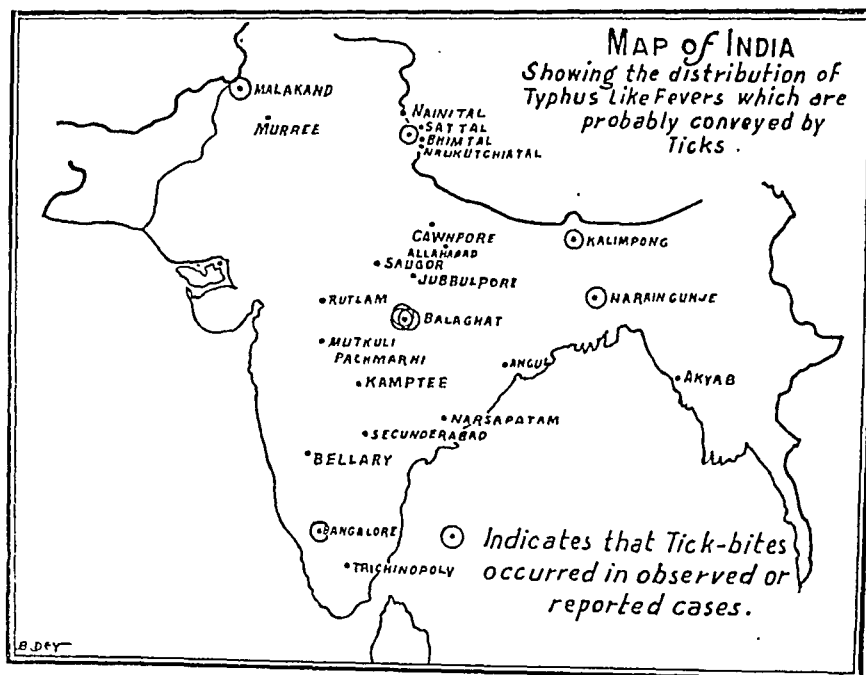

4. Norfolk—Virginia—The case described by Dr. R. R. Spencer in 1927.

In addition to these there are many other cases in which there is a strong suggestion that ticks had bitten the patients, but in these the association with tick-bite has not been proved to occur.

of person-to-person infectivity such as would be expected to occur in a louse-borne disease. Actual evidence of the arthropod vector is surprisingly scanty, apart from the cases reported by the senior author from India and Spencer's case from Norfolk, Virginia.

The Weil-Felix reaction in Typhus-like fevers.

The great variations in the Weil-Felix reaction are remarkable. Fletcher's interesting

These examples of sporadic typhus-like fever from India and other parts of the world show that a fever of the typhus-group occurs quite commonly in many places under conditions which are entirely dissimilar to those which are usually associated with louse-borne typhus. The common features of the disease are low mortality, failure to infect guinea-pigs, and a total absence of evidence

observations show that all of his cases gave a negative response to one or other of the strains of *B. proteus* X 19, and also that all of the cases were positive to some of the strains used, so that if only one strain of the organism had been employed the results would have been bewildering.

The paper by Wilson of Belfast in the *Journal of Hygiene* of July 1927 is of

special interest in connection with the serology of the fevers of the typhus group. Wilson was the originator of the agglutination test for typhus fever and therefore his findings are of exceptional importance.

He found great variations in the response of various strains of *proteus* X 19 to serum from European cases of typhus; some of the strains gave the reaction in high dilutions to some samples of serum, while others gave the reaction in low dilutions and the results were by no means consistent with each other.

On the whole the "Kingsbury" strain received from Dr. Fletcher was very insensitive to serum from European cases of typhus, and Wilson's original *agglutinabilis* strain of bacteria was more sensitive than *B. proteus* X 19. The following are two examples of the variations in agglutination response found by Wilson:—

	Strain "0."	Jerusalem Strain.	Strain 67.	Warsaw Strain.
Serum 1	+++1 : 80	-1 : 40	++ +1 : 160	-1 : 40
Serum 2	++1 : 320	++1 : 80	++1 : 640	++ +1 : 320

The conflicting results obtained by Burnet and Olmer, have already been described. The evidence all points to such a variability in the agglutination response that it seems doubtful whether much importance can be attached to the Weil-Felix test for the classification of the typhus-like fevers, until some order can be evolved from the state of confusion which exists at present. The failure to infect guinea-pigs and other animals would suggest that the fevers do not belong to the typhus group at all, at any rate to the ordinary louse or tick-borne forms of the disease, but the clinical evidence is so overwhelming that these failures cannot be accepted as proof that the diseases belong to another group. The failure to produce symptoms of tsutsugamushi disease in inoculated field mice, although the inoculated mice can be proved to be infective, may have some bearing on this question, and obviously further study is needed before we can form a true estimate of the significance of animal experiments in cases of fevers of the typhus group.

Laboratory findings have hitherto been regarded as offering absolute criteria by which we can determine the nature of typhus and allied fevers; it is now evident that these supply conflicting evidence.

It is obvious that sporadic cases of typhus-like fever occur in many widely separated places in the world, and while some of these may be explained as sporadic louse-borne typhus, it is exceedingly unlikely that the louse is the vector of all or even of majority of the cases,

The Part Played by the Tick.—The spotted fever of the Rocky Mountains has been proved to be conveyed by the tick, and although this disease is very closely related to louse-borne typhus in clinical manifestations and pathology we are fully justified in classifying it as a distinct type of fever and in calling it "tick-typhus."

A definite association with the bite of a tick has been shown to occur in eight of the Indian cases of sporadic typhus-like fever; nearly all of the other cases have occurred under conditions in which louse conveyance could be excluded and tick-bite was very likely to occur. One point which has to be determined is whether ticks can attach themselves to the body for a sufficient length of time to introduce infection and then drop off without having been observed.

This hypothesis does not seem to be inherently improbable: a tick-bite is usually painless, man is not the host of choice of ticks and so it is quite possible that the tick may feed on man only when a more congenial host is not available; and it may find the smooth human skin unsuitable for a prolonged stay. In several of the cases in which ticks were found in situ after the fever had appeared they were situated in such protected places as the umbilicus, the scrotal skin, and the external auditory meatus. It is quite possible that disturbance by friction of the clothing may cause the dislodgment of ticks which happen to bite other parts of the body.

A point which suggests that undetected tick-bite may frequently occur is that we have often been told that ticks never bite human beings in certain localities, yet we have soon found from personal experience that they do so. Ticks had not been suspected of conveying disease to human beings except in some well defined areas in which Rocky Mountain fever, tick relapsing fever and tick paralysis are known to occur, hence medical men seldom enquire into the question of tick-bite, the layman also does not look for ticks and so they are very likely not to find them unless they obtrude themselves on their attention.

Taking into consideration the known facts that the tick conveys a typhus-like fever known as Rocky Mountain fever, and that not less than eight cases of a similar disease have been seen in which the onset of the fever occurred in India within a few days of bite by a tick, it is reasonably certain that the tick can convey a typhus-like fever in India. This disease may be identical with the Rocky Mountain fever, at any rate it is closely related to that disease.

The name tick-typhus is more appropriate to the fevers of the typhus-group which are known to be conveyed by ticks than the

other names which have been suggested such as Rocky Mountain fever.

The other cases of sporadic typhus-like fever in India which resemble tick-typhus in their clinical and epidemiological features are likely to be conveyed by ticks, as the only other probable vector—the mite—causes a local sore and lymphadenitis in the great majority of cases; the type of locality affected is different, and no evidence of mite infestation has been discovered in the Indian cases.

A mite or other arthropod may well be found to convey a typhus-like fever in India, but unless the mite-typhus of India differs greatly in its symptomatology from the cases seen in other parts of the world it is unlikely that mites are responsible for the Indian cases which have been recorded.

In the cases of sporadic typhus-like fever which have been reported from other parts of the world the evidence for tick transmission is much less definite.

Apart from the classical Rocky Mountain fever there is only one case recorded outside India in which typhus-like fever followed a bite by a tick, viz. the case from Norfolk in Virginia, reported by Spencer in 1927.(10)

In the typhus-like fevers described by McNaught as "paratyphoid," ticks were suspected by Col. Maher to have some connection with the disease so that presumably ticks were known to have bitten some of the patients. Of the other recorded cases all that can be said is that they occurred under conditions in which tick-bite was more likely to occur than the bite of any other arthropod, lice and mites included.

The cases reported by Maxcy in Alabama and Savannah(11) would at first sight appear to contradict this suggestion because they occurred in persons living in large centres of population. It would be interesting to discover how many of the patients had been in the habit of spending their Sundays and holidays in the woods and open country. People of the social stratum which was chiefly affected would be likely to go into the wilds by the automobile which is universal in America to-day.

We know where the patients lived and worked, but we are told nothing about where they spent their Sundays and other holidays. Maxcy has excluded lice, he suggests ticks, mites and fleas as being worth considering, and while we agree with him generally, we are inclined to regard ticks as the most likely of the three vectors which are mentioned.

The Marseilles group of typhus-like fevers(12) is of interest; it is a curious fact that a few days before reading the report of this disease in the French lay press, the senior writer came across a case of tick-bite in a human being in the South-West of France at about the same latitude as Marseilles.

The relationship between Louse-typhus, Tick-typhus and Mite-typhus.

Till recently there was very little tendency to emphasize the relationship between typhus, Rocky Mountain fever and Japanese river fever: the work of Ricketts and Wolbach has demonstrated that the pathology of the former two diseases is so similar that there can be no reasonable objection in classing them as members of one disease group. Recent work on the Japanese fever suggests that it is of the same type, and therefore the senior author felt justified in suggesting that all the typhus-like fevers should be united in one "typhus group" and that the members of the group should be called louse-typhus, tick-typhus, mite-typhus and typhus of unknown vector. Criticism was anticipated from those who have described the three diseases as distinct entities, but it was surprising to find that Dr. E. W. Goodall now attacks those who would differentiate the members of the typhus group of fevers. Dr. Goodall contends that the fevers are typhus, whatever the arthropod vectors may be. Classification should always serve a useful purpose and if the diagnosis and prevention of all the fevers of the typhus group were on the same general lines there would be no object in subdividing the group. But we can hardly imagine two diseases which are more dissimilar in respect of the conditions under which they are conveyed than louse-typhus and tick-typhus: correspondingly the methods of management of the patients are quite different and so are the measures of prevention. Also it is probable that there are specific differences in the virus of the two diseases. In any case it would appear to be reasonable to apply the name of the vector when this is known, while in cases of doubt the disease can be called a "typhus group fever."

Ancestry of the Rickettsia Bodies.

In a previous paper (*Indian Medical Gazette*, February 1924) the suggestion was made by the senior writer that the virus of tick-typhus and that of louse-typhus might have a common ancestry and that either virus might exceptionally be conveyed by both arthropod vectors instead of solely by one.

In the case of sporadic typhus-like fevers there is rarely any evidence that person-to-person communication occurs, but there was one "household" outbreak in the series reported by Lt.-Col. McKechnie which could be explained more readily by the hypothesis of louse-infection than by that of infection by ticks of the forest.

The experiments of Nicolle and Anderson (13 and 14) on Spanish relapsing fever are suggestive in this connection; these workers found that the infection which was normally tick-conveyed could also be communicated
